Abstract

Parasitic nematodes infect over one quarter of the population worldwide, causing morbidity in over one billion people. Current anthelmintic drugs are beginning to lose effectiveness due to the presence of resistant strains. We are interested in the role of neuropeptides, which regulate behaviors in all organisms, as another possible target for anthelmintic drugs. FMRFamide-related peptides (FaRPs) are a family of neuropeptides that are conserved throughout the animal kingdom. In particular, nematodes contain the largest family of FaRPs identified thus far and many of these FaRPs are identical among different nematode species; FaRPs in nematodes are collectively referred to as FLPs (FMRFamide-like peptides). However, little is known about the function of these FLPs. We are using the non-parasitic nematode *Caenorhabditis elegans* as a model for examining FLPs in nematodes. *C. elegans* contains at least 31 *flp* genes that encode 72 potential FLPs. Among the *flp* genes, *flp-1* is one of the few that is universally found in nematodes. FLP-1 neuropeptides were previously reported to be involved in sensory and motor functions. However, previous alleles of *flp-1* also disrupted a neighboring gene, *daf-10*. To understand the phenotypes of *flp-1*, new alleles that specifically disrupt *flp-1* were characterized. The previously reported locomotory and egg-laying defects were found to be due to loss of *flp-1*, while the osmolarity defect is due to loss of *daf-10*. In addition, loss of *flp-1* and *daf-10* both cause several phenotypes that increase in severity in the double mutants by disrupting different neurons in the neural circuits.

Introduction

An estimated 1.5 billion people, comprising 24% of the world’s population, are infected with soil-transmitted helminthes [1]. Among the most prevalent infections worldwide, an estimated 807 to 1,221 million people are infected with large roundworms (*Ascaris lumbricoides*) [2], 576
Neuropeptides are involved in most complex behaviors of multi-cellular organisms. Nematodes, specifically, have a larger complement of neuropeptides than other organisms [17,18]. Our focus is on the family of FMRFamide (Phe-Met-Arg-Phe-NH₂)-related peptides (FaRPs), which was first isolated as a cardioactive agent in mollusks [19]. Since then, a large family of FaRPs, which share a common RFamide C-terminus, has been identified throughout the animal kingdom where they affect diverse functions [20]. Of particular note, nematodes appear to produce the largest numbers of FaRPs among animals; FaRPs in nematodes are collectively referred to as FLPs (FMRFamide-like peptides). For instance, at least 31 flp genes encode FLPs in C. elegans, where FLPs have been found to have effects on locomotion, egg laying, sleep, and different sensory modalities [18]. As most FLPs have no mammalian counterparts, FLPs and their signaling pathways might provide a useful target for new anthelmintic drugs. With the exception of one receptor in the pond snail [21], FaRPs signal through G protein-coupled receptors [17]. The functions of distinct FaRPs and their signaling pathways are still not completely understood [17,22,23].

flp-1 is one of the few flp genes that is universally found in nematodes [18], making the FLP-1 signaling system an attractive target for anthelmintic drugs. We previously reported that the deletion of flp-1 caused numerous behavioral defects in C. elegans, including a reduced response to being touched on the nose, a reduced sensitivity to hyperosmolarity, locomotory defects, and an increased tendency to wander off a food source [22]. flp-1 mutants were also found to have egg-laying defects [24], which were potentiated in the presence of serotonin [25]. Hence, modulating FLP-1 levels causes effects on mobility and reproduction, thereby increasing its interest as a potential drug target. The flp-1 gene lies in the first intron of daf-10, which was not apparent until the genomic region of daf-10 was defined [26]. daf-10 encodes a component of the intraflagellar transport complex A (IFT-A) and is responsible for transport of particles in the cilia of amphidial and phasmid sensory neurons [25–27]. As a result of improper cilia formation, mutations in daf-10 cause C. elegans to have reduced sensitivity to hyperosmolarity [28]. Because the initial flp-1 alleles, yn2 and yn4, also deleted part of daf-10, some of the initial behaviors attributed to FLP-1 peptides [22] may be caused by loss of daf-10 activity. To clarify which behaviors are due to loss of flp-1, we characterized the behaviors of recently isolated flp-1 single mutants and compared these behaviors to those in daf-10 single and daf-10 flp-1(yn2) double mutants. Our results indicate that FLP-1 peptides are involved in nose touch sensitivity, locomotion, and reproduction, making its signaling pathway a potential target for new anthelmintics.
Materials and methods

Maintenance of strains

All nematodes were grown and maintained at 20°C according to Brenner [29] with modifications. N2 is the wild-type Bristol strain [29]. Other strains used include: LGIII: tax-4(p678); LGIV: flp-1(ok2811, ok2781, and ok2505), daf-10(gk795 and e1387), daf-10 flp-1(yn2).

PCR and generation of transgenic animals

To determine how the different deletions in the flp-1 alleles affected the transcripts, we isolated RNA from the different flp-1 alleles, reverse transcribed the RNA with an oligo dT primer, and amplified the flp-1 transcript with primers MR28 (5’-GAATTCACTTTATCAGCTCTGC TCTACCAGGTTAGGT-3’) and 33P2 (5’-GGATTCACGATCGAAG TTGTC-3’), which encompasses the region between the initiator and stop codons. Amplified products were excised and the DNA sequence determined commercially (Genewiz).

Generation of transgenic lines. To generate constructs to test for rescue of flp-1 phenotypes, genomic DNA was amplified with primers MR44 (5’-CACAGTTCGTTTA CATAC-3’) and 33P8 (5’-TGCTCCATGGTG GAGAGC-3’), and subcloned into a TA vector (Invitrogen). The resultant clone was digested and subcloned into pB3-SB, which contains a 5.25 kbp fragment of the flp-1 genomic region, to generate the plasmid pLN/B3-SB, which contains 6 kbp of the flp-1 promoter, the entire flp-1 coding region, and 2.3 kbp downstream of the flp-1 3’UTR [22]; pLN/B3-SB was digested with HindIII and re-ligated to generate the plasmid pLN/B3H, which contains the same flp-1 coding and downstream regions as pLN/B3-SB, but only 4 kbp of the flp-1 promoter region. All transgenic lines, except ynEx224 and ynEx228, were generated as described [30] by co-injecting the pLN/B3-SB plasmid and the SUR-5::GFP marker (injected at 50 ng/μl) [31]; ynEx224 and ynEx228 were similarly generated except that the pLN/B3H plasmid was used. Multiple independent transgenic lines were generated for the different flp-1 and daf-10 alleles. Ex alleles indicate transgenic animals carrying extrachromosomal arrays, while Is alleles indicate transgenic animals with integrated transgenes; extrachromosomal arrays were integrated into the genome as described [30] with slight modifications; the insertion site was not mapped. The transgenic lines include: 1) lines injected at plasmid concentrations of 10 ng/μl: ynEx218, ynEx219, ynEx220, ynEx221, ynEx222, ynEx223, 2) lines injected at plasmid concentrations of 20 ng/μl: ynEx224, ynEx225, ynEx226, ynEx228, ynEx229, ynIs118; and 3) lines injected at plasmid concentrations of 50 ng/μl: ynEx217, ynEx227.

Behavioral assays

All assays were done on day-old adult hermaphrodites unless otherwise specified. Animals were picked at the fourth larval stage and grown at 20°C for approximately 24 hours prior to performing the assay.

Locomotion assays

Movement on a solid surface. To prepare plates for scoring movement on a solid surface, 100 microliters of E. coli (OP50/1) was spotted onto a MYOB plate [32] and grown overnight. The next day, a stamp (made by cutting a 1 cm square from the center of a 30 mm Sylgard circle) was applied to the bacterial lawn, leaving an even 1 cm square bacterial lawn. Ten to twenty day-1 adult worms were transferred to the bacterial lawn and left on an Nikon SMZ1000 stereomicroscope stage for 5 minutes to allow the worms to acclimatize to ambient oxygen levels and temperature. The movement of the animals was subsequently recorded at 8X magnification with a Nikon DS-F11 camera using Nikon Instruments Software-Elements Advanced Research.
(NIS-Elements AR) for 5–10 minutes. The number of body bends was counted for 1 minute starting at the 2-minute interval in the video.

Photographs of day-1 adult worms moving on bacterial food sources were also taken on a Nikon SMZ1000 stereomicroscope with a Nikon DS-F11 camera at 40X magnification. The wavelength and wave height (2x the amplitude) of the tracks in the bacterial lawn were calculated with the NIS-Elements AR imaging program. Five measurements were taken for each animal, averaged, and a mean value for each animal was determined.

**Movement in liquid.** To assess the effects of serotonin on movement [33], individual worms were transferred to a microtiter well containing serotonin solution (5 mg serotonin/ml M9 buffer; Sigma). After approximately 15 minutes in the serotonin solution, the number of body bends completed in 15 seconds was counted as modified from Miller et al. [34]. Each individual animal was counted three times and the three values were averaged to give a mean number for each animal.

**Reproductive phenotypes**

To determine an egg-laying rate, day-1 adult worms were singly plated and allowed to lay eggs for 2 to 8 hours. The number of eggs laid was counted and the egg-laying rate per hour was calculated. To determine the number of eggs retained in the uterus, day-2 adults were used. 50 microliters of a weak hypochlorite solution (1.2 ml of 6% NaOCl solution (Clorox), 0.5 ml 5 N KOH, and 8.3 ml water) was added to individual rings on the lid of a microtiter plate; individual day-2 worms were transferred to the rings. After the body of the worm was dissolved by the hypochlorite solution, the number of eggs was counted.

**Nose touch**

The nose touch response was performed as described [35]. Each day-1 adult was tested three times and the three values were averaged for each animal.

**Osmotic avoidance**

The ring assay for osmotic avoidance [28] was done with 10 worms in a 1.5 cm ring of 6 M glycerol (dyed with blue as described [22]). The number of animals within the ring was counted after 10 minutes.

**Wandering**

To assay whether animals stay on a food source, 10–20 day-1 adults were placed on a plate with a bacterial food source. The number of animals on the plate was counted at 12 hour intervals for a total of 48 hours.

**Statistical analysis**

All statistical analyses were carried out using Prism software (GraphPad). Values from wild-type, mutant, and/or transgenic animals were compared using a one-way ANOVA/Kruskal-Wallis and Tukey or Dunn’s posthoc test, depending on whether the values passed a normality test.

**Results**

The *flp-1* gene encodes eight peptides within exons 3 to 6 (Table 1) and is alternatively spliced, giving rise to transcripts A, B, and C [36,37], which encode 7, 6, and 4 distinct FLP-1 peptides, respectively; all transcripts also encode a related, non-FLP-1 peptide [22]. The initial *flp-1*
alleles, yn2 and yn4, also deleted part of the daf-10 gene, making it difficult to determine which phenotypes correspond to loss of flp-1 and which to loss of daf-10 (Fig 1). The isolation of additional alleles that only disrupted flp-1 by the C. elegans Knockout Consortium allowed us to definitively categorize the phenotypes associated with loss of flp-1.

The flp-1 (ok2811, ok2781, and ok2505) alleles contain deletions that affect different splice sites or exons within the first three exons (Fig 1), making it difficult to predict a priori how transcripts would be affected. Hence, we performed multiple reverse transcription-polymerase chain reactions (RT-PCRs) for each allele, so that all possible transcripts would be isolated, and determined the DNA sequence of the products. For ok2811 mutants, the deletion affected the splice site at the end of exon 1 and extended past exon 2; the resultant transcript contained intronic sequences and disrupted the reading frame, suggesting that ok2811 is a null allele; no other transcripts were identified. The ok2781 deletion affected splicing at the 5’ end of exon 2 and extended into intron 2; the resultant transcript included intronic sequence but maintained the reading frame, suggesting that ok2781 mutants will have phenotypes similar to wild type; no other transcripts were detected. The ok2505 deletion extended from intron 2 to intron 3, thereby removing exon 3; however, the resultant transcripts used cryptic splicing sites, resulting in two transcripts in which the coding sequences for two (KPNFMRFY-NH$_2^2$ and AGSDPNFLRF-NH$_2^2$) to four (KPNFMRFY-NH$_2^2$, AGSDPNFLRF-NH$_2^2$, SQPNFLRF-NH$_2^2$, and AGSDPNFLRF-NH$_2^2$) FLP-1 peptides were deleted relative to transcript A. Hence, the three alleles were predicted to represent a presumptive null (ok2811), a presumptive wild type (ok2781), and a partial loss-of-function (ok2505). Transcription of daf-10 was not affected by the flp-1(ok2811, ok2781, ok2505) deletions by RT-PCR (S1 Fig).

### Loss of flp-1 or daf-10 causes sensory defects

The daf-10 flp-1(yn2 and yn4) double mutants showed defects in two sensory modalities: mechano- and osmosensation. Wild-type animals recoil when touched on their nose (nose touch sensitivity) [35]; this nose touch response is mediated by the ASH multimodal sensory neuron [38]. While wild-type animals respond to nose touch 97% of the time (N = 371), all three flp-1 mutant alleles showed a significant decrease in the nose touch response (ok2811, ok2781, and ok2505 responded 72%, 68% and 55% of the time, respectively), although none of the decreases were as severe as the yn2 allele, which responded only 7% of the time (Fig 2; Table 2). The nose touch defect was rescued by wild-type flp-1 in the ok2781 and ok2505 mutants. Because daf-10 mutants have defective sensory cilia, we expected that the mutants

*x = no. of copies, italics = non-RFamide peptide, m = additional peptides missing in alternative transcripts
^Although WormBase predicts a transcript C, we have not been able to isolate this transcript by RT-PCR.

https://doi.org/10.1371/journal.pone.0189320.t001
**Fig 1.** The genomic organization of the *flp-1* gene. *flp-1* consists of six exons encoding seven FLP-1 peptides and one related non-FLP peptide; exons 3 to 6 contain the peptide-coding regions. The *flp-1* allele, *yn2*, is a 1.1 kbp deletion that removes 567 bp of the promoter region and extends through most of exon 4. No *yn2* transcripts were detected by reverse transcription-polymerase chain reaction. The *ok2811* mutation disrupts the splice donor site of exon 1, leading to improper splicing and the inclusion of intronic sequence in the transcript. Only one transcript was detected. The reading frame is disrupted, suggesting that *ok2811* is a null allele. The *ok2781* deletion disrupts the splice acceptor site of exon 2, leading to the use of a cryptic splicing site and inclusion of intronic sequence in the transcript; only one transcript was detected. The reading frame is maintained. The deletion in *ok2505* extends from intron 2 to intron 3; two transcripts are produced, both of which maintain the reading frame but result in the loss of two to four peptides relative to transcript A. *flp-1* and *daf-10* exons are indicated as teal and grey boxes, respectively; only four of the 18 *daf-10* exons are shown. The arrows indicate the direction of transcription; the bars indicate the extent of the deletions.

https://doi.org/10.1371/journal.pone.0189320.g001
would show no nose touch sensitivity, similar to the yn2 double mutants. Accordingly, the daf-10 mutants were nose touch insensitive and had slightly, but not significantly higher (17–19%) response rates than yn2 mutants, and significantly lower response rates than the flp-1 mutants (Fig 2; Table 2; Dunn’s posthoc test, p < 0.0001). These results suggest that loss of flp-1 slightly exacerbates the sensory loss in the nose touch circuit in daf-10 mutants.

Wild-type animals are highly sensitive to environmental conditions. For instance, C. elegans avoids areas of high osmolarity [28] and will avoid crossing a high osmolarity ring (97% within ring; N = 168; no. trials = 16; Table 2). yn2 double mutants are insensitive to high osmolarity (11% within ring; N = 140; no. trials = 14; [22]). Similarly, daf-10 single mutants showed no response to high osmolarity (19% and 17% within ring for e1387 and gk795, respectively; N = 150; no. of trials = 15; Table 2). By contrast, all flp-1 single mutants were sensitive to high osmolarity (81%, 84%, and 92% within ring for ok2811 (N = 150; no. of trials = 15), ok2781 (N = 161; no. of trials = 16), and ok2505 (N = 150; no. of trials = 15), respectively), indicating that the osmolarity defect in yn2 double mutants is due to loss of daf-10 alone.
Table 2. Loss of flp-1 causes multiple defects.

Increased levels of FLP-1 peptides decrease locomotion

In its natural habitat, *C. elegans* moves between soil and liquid, depending on the moisture in the soil. To mimic these conditions in the laboratory, we assayed crawling and swimming movement of animals on an agar surface, which is analogous to soil, and in liquid, respectively. We previously reported that *yn2* double mutants showed hyperactivity and a larger waveform when crawling compared to wild type, while overexpression of *flp-1* inhibited movement and showed a smaller waveform [22]. Here, we further dissected the locomotory patterns of *yn2* double and *flp-1* single mutants. Movement of *yn2* double mutants is bimodal. When *yn2* double mutants are measured only in their locomotory phase, they demonstrate hyperactivity as reported in Nelson et al. [22] and showed a larger waveform than wild type (Fig 3A; Table 2). However, *yn2* double mutants also showed long periods of inactivity interspersed with rapid movements; for instance, 59% of *yn2* double mutants (n = 134) showed no forward movement during our 1 minute analysis, whereas only 7% of wild-type animals (n = 358) showed no forward movement. Therefore, if movement was measured as activity for a specific length of time, such as one minute, *yn2* double mutants showed hyperactivity, similar to *daf-10* mutants (Fig 3B; Table 2). The single *flp-1* mutants, *ok2811* and *ok2781*, showed increased crawling mobility and larger waveforms (Fig 3A and 3B; Table 2). Hence, the locomotion phenotype of *yn2* double mutants is the combined result of the lack of sensory input due to the *daf-10* mutation and the hyperactivity due to loss of FLP-1 peptides. In contrast to the hyperactive movements of *ok2811* and *ok2781* mutants, *ok2505* mutants were very sluggish (Fig 3B; Table 2) and showed decreased movement. Because *ok2505* mutants are predicted to express only a subset of the FLP-1 peptides, these results suggest that different FLP-1 peptides have different effects on the locomotory circuit.

Exogenous serotonin inhibits locomotion in *C. elegans* [33]. Wild-type animals exposed to exogenous serotonin stop swimming within minutes (Fig 3C; Table 2). *yn2* double mutants were insensitive to the serotonin-induced sluggishness [22]. To determine whether this serotonin-insensitivity is due to loss of *flp-1* or *daf-10*, single *flp-1* and *daf-10* mutants were similarly exposed to exogenous serotonin. Like wild-type animals, *daf-10* mutants stopped swimming in the presence of serotonin. By contrast, all *flp-1* mutants continued swimming in the presence of serotonin (Fig 3C). The swimming phenotype was rescued by a wild-type *flp-1* fragment. Hence, the serotonin-insensitivity is due to loss of FLP-1 peptides.

*yn2* double mutants, have an additional sensory-motor phenotype, which we termed wandering. Wild-type animals stay on a bacterial food source; however, *yn2* double mutants wander off the food source and up the side of the plate, where they die [22]. The wandering phenotype is not due to the loss of chemosensory input, as *yn2* double mutants can chemotax to a bacterial food source [22]; furthermore, *daf-10* single mutants, which have impaired sensory responses, and *flp-1* mutants did not exhibit wandering (Fig 4). To determine whether the wandering phenotype was a result of loss of sensory input and *flp-1* signaling, we mated *flp-1* (*ok2811*) mutants with a second mutant that has decreased sensory responses, *tax-4*. *tax-4* encodes a subunit of a cyclic nucleotide-gated channel that is homologous to the vertebrate rod photoreceptor cGMP-gated channel and that is found in a subset of sensory neurons; loss of *tax-4* results in defects in several sensory behaviors [39]. The *tax-4*; *flp-1* double mutants showed a wandering behavior, although not as robustly as the *yn2* mutants. We suggest that wandering is the result of a synergistic interaction between loss of sensory input and FLP-1 signaling in downstream circuits.

Increased levels of FLP-1 peptides decrease egg-laying rates

Wild-type animals lay between 5–8 eggs per hour [22], but the rate of egg laying is highly affected by environmental stresses and the animal’s metabolic rate. For example, under harsh
Fig 3. FLP-1 peptides modulate locomotion. Loss of flp-1 causes hyperactivity, while overexpression of flp-1 decreases activity. Both the amplitude of the sinusoidal waveform (A) and movement rate (B) were affected. In addition, while exogenously applied serotonin inhibits swimming in wild-type animals, flp-1 mutants continued to swim in the presence of serotonin (C). daf-10 IFT-A mutants showed a decreased locomotory activity and were responsive to the inhibitory effects of serotonin. Mean±SEM, solid, colored bars (except black) represent mutant alleles, hatched bars represent transgenic lines. Ex alleles indicate a transgenic animal with an extrachromosomal array, while Is alleles indicate transgenic animals with integrated transgenes. Significantly different from wild type: ***.
environmental conditions, such as low food availability, high osmolarity, and high vibration frequency, egg-laying rates are decreased [40]. yn2 double mutants had a severely decreased egg-laying rate of roughly one egg per hour (Fig 5A; Table 2). All of the single flp-1 mutants also showed a significantly decreased egg-laying rate, although none showed phenotypes as severe as that in the yn2 double mutants. Rather than being rescued by microinjection of a wild-type flp-1 fragment, the transgenic flp-1 mutants as well as the yn2 double mutants showed an even more severe egg-laying defect. The daf-10(e1387) allele also showed a significantly decreased egg-laying rate, which was not seen in the daf-10(gk793) allele.

The decreased egg-laying rate in flp-1 mutants can result from several variables: mutants are generating fewer eggs, a sensor controlling the number of eggs in the uterus is defective, or muscles are not responsive to the HSN and VC motor neuron output [40]. To determine whether the decreased egg-laying rate was due to a decreased number of available eggs for release, we counted the number of eggs in the uterus. Wild-type animals have 10–15 eggs in their uterus at any one time [40,41], although we had slightly higher numbers in our current assays (2 day adults: 15.91±0.55 (N = 113); Fig 5B; Table 2). The yn2 double and ok2811 null mutants did not show any significant differences compared to wild type. By contrast, the ok2781 and ok2505 mutants showed significantly fewer and significantly greater numbers of retained eggs, respectively (Fig 5B; Table 2). Microinjection of the flp-1 fragment significantly increased egg retention in all flp-1 mutants (Fig 5B; Table 2). Loss of daf-10 significantly decreased egg retention but only slightly decreased egg-laying rates. Overexpression of flp-1 in the daf-10 mutants, however, increased egg retention.

The decreased egg-laying rate in flp-1 mutants can result from several variables: mutants are generating fewer eggs, a sensor controlling the number of eggs in the uterus is defective, or muscles are not responsive to the HSN and VC motor neuron output [40]. To determine whether the decreased egg-laying rate was due to a decreased number of available eggs for release, we counted the number of eggs in the uterus. Wild-type animals have 10–15 eggs in their uterus at any one time [40,41], although we had slightly higher numbers in our current assays (2 day adults: 15.91±0.55 (N = 113); Fig 5B; Table 2). The yn2 double and ok2811 null mutants did not show any significant differences compared to wild type. By contrast, the ok2781 and ok2505 mutants showed significantly fewer and significantly greater numbers of retained eggs, respectively (Fig 5B; Table 2). Microinjection of the flp-1 fragment significantly increased egg retention in all flp-1 mutants (Fig 5B; Table 2). Loss of daf-10 significantly decreased egg retention but only slightly decreased egg-laying rates. Overexpression of flp-1 in the daf-10 mutants, however, increased egg retention.

Fig 4. Loss of sensory input and flp-1 signaling is responsible for the wandering behavior. Wild-type animals remain on a bacterial food source; animals that move off a food source and do not return are considered wanderers. daf-10 flp-1 and tax-4; flp-1 double mutants are wanderers, while the single flp-1, daf-10, and tax-4 mutants do not wander. For the tax-4(p678) and tax-4(p678); ok2811 strains, animals were not scored at each time point, giving rise to some fluctuation in the data. 3–5 trials for each strain; at least 30 animals were tested for each strain.

Fig 5. Modulation of *flp-1* affects reproductive functions. Loss and overexpression of *flp-1* decreased egg-laying rates (A), suggesting that different FLP-1 peptides modulate the egg-laying circuit differently. Loss and overexpression of *flp-1* generally increased the number of eggs retained in the uterus (B), again suggesting that individual FLP-1 peptides affect egg retention differently. Loss of *daf-10* IFT-A function also affects reproduction. Mean ± SEM, at least 43 or 24 mutants or transgenic mutants, respectively, were tested in at least 3 independent trials; solid, colored bars (except black) represent mutant alleles, hatched bars represent transgenic lines. *Ex* alleles indicate a transgenic animal with an extrachromosomal array, while *Is* alleles indicate transgenic animals with integrated transgenes. Significantly different from wild type: ***, p≤0.001, Tukey’s post hoc test; transgenic line significantly different from mutant allele: ***, p≤0.001, **, p≤0.01, *, p≤0.05, Tukey’s post hoc test. ND = not determined.

Discussion

In identifying new drug targets for anthelmintic drugs, peptide signaling systems that inhibit locomotion or reproduction are attractive targets. FLP-1 neuropeptides were previously found to have roles in locomotion and egg laying [22,24]. Because the flp-1 gene lies within the first intron of the daf-10 gene and the initial flp-1 alleles, yn2 and yn4, affected the activity of both flp-1 and daf-10, we examined more recently isolated single flp-1 alleles for sensory, locomotory, and reproductive defects. Surprisingly, although the ok2781 mutants were predicted to have wild-type behavior because no peptide coding regions are lost, the mutants acted more as loss-of-function mutants, more often showing phenotypes similar to or less severe than ok2811 mutants, which are the presumed flp-1 null mutants. These results suggest that some FLP-1 peptides are still expressed, albeit at low levels, in ok2781 mutants. The phenotypes of ok2505 mutants varied greatly compared to ok2811 mutants, sometimes showing more severe phenotypes (e.g., nose touch response, crawling rate, resistance to serotonin, and number of eggs retained in the uterus) and sometimes acting similar to wild-type (e.g., waveform), suggesting that the different FLP-1 peptides affect neural circuits differently. Because ok2505 mutants expressed only a subset of FLP-1 peptides, we cannot distinguish at this time which FLPs promote and which inhibit different behaviors.

DAF-10 IFT-A is required for proper cilia formation in amphid and phasmid neurons in C. elegans [26,42]. The cilia, which are located at the distal endings of the dendrites, contain the molecular machinery for sensory transduction and translating information from the environment [26]. The loss of DAF-10 IFT-A causes the animals to have defects in osmo- and chemosensitivity [42], whereas flp-1 single mutants have no osmolarity defect. Hence, the osmolarity defect previously reported in the yn2 double mutants as caused by flp-1 [22] was actually due to the loss of daf-10.

The ASH sensory neuron, whose sensory cilia are functionally dependent on DAF-10 activity, mediates two distinct sensory stimuli: nose touch and avoidance of noxious chemicals and hyperosmolarity; activation of ASH results in signaling to AVA interneurons, the driver cells for backward locomotion, causing the animal to initiate a reversal [43]. However, nose touch and avoidance to noxious chemicals activate distinct cellular signaling pathways, so that loss of one ASH sensory modality does not imply loss of other ASH sensory modalities [43]. yn2 double mutants were not responsive to nose touch or hyperosmolarity [22], whereas flp-1 mutants were nose touch insensitive, but hyperosmolarity sensitive. flp-1 is expressed in the AVA interneuron [22]. Because the yn2 double mutant has a more severe nose touch insensitivity than the single mutants alone, we propose that the enhanced nose touch defect in the yn2 double mutants is due to the reduction of the ASH signal due to the faulty cilia in daf-10 mutants, compounded by the reduction of downstream AVA interneuron signaling caused by the loss of flp-1. Alternative signaling pathways mediate the hyperosmolarity response in flp-1 mutants.

Disrupted sensory input and exogenous serotonin decrease locomotion [33,44]. The locomotory activity of yn2 double mutants was further characterized. The yn2 double mutants displayed extended periods of inactivity, which we attribute to loss of daf-10, as the daf-10 single mutants show a similar phenotype. When the double mutants were active, the speed with which they moved [22] and the sinusoidal waveform they exhibited were much greater than that of wild type. flp-1 single mutants, ok2811 and ok2781, were also hyperactive and had exaggerated waveforms (Fig 3A and 3B; Table 2). Hence, the speed and waveform defects are due to loss of flp-1. The slowed speed and wild-type waveform of ok2505 mutants suggests that different FLP-1 peptides have different effects on locomotory circuits. Our results do not differentiate between whether the lost FLP-1 peptides in ok2505 mutants activate locomotion or the remaining peptides inhibit locomotion. Both the yn2 double mutants and flp-1 single mutants...
were insensitive to the serotonin-induced decreased locomotion, whereas the daf-10 single mutants stop swimming in the presence of exogenous serotonin. Collectively, our results indicate that the overall activity of FLP-1 peptides, like serotonin, is to inhibit locomotory circuits. These flp-1 locomotory circuits can over-ride the locomotory circuits in which serotonin is active, as flp-1 mutants continue to swim in the presence of serotonin while wild-type and daf-10 single mutants stop swimming.

When C. elegans are starved, they become more active as they constantly forage for food [45]. Often times, starved animals wander off the agar medium and climb onto the side of plates where they die, a phenotype we refer to as wandering. flp-1 and daf-10 single mutants do not wander. By contrast, the yn2 double mutants, which can sense food [22], climb onto the side of plates even in the presence of food. We suggest that wandering in yn2 double mutants is a synergistic effect caused by the loss of sensory input due to the knockout of daf-10 and the loss of downstream interneuron signaling by flp-1. Similarly, decreasing sensory input by a different mutation, such as tax-4, in flp-1 mutants also caused a wandering phenotype. Because tax-4 is only expressed in a subset of amphidial neurons [39] and DAF-10 is expressed in all amphidial neurons, we predicted and found that the wandering phenotype was not as severe in tax-4; flp-1 double mutants.

The yn2 double mutant has a severe egg-laying defect [22]. Because only one daf-10 allele showed a decreased egg laying rate, we conclude that loss of amphidial and phasmid sensory input affects egg-laying rates only slightly. By contrast, flp-1 single mutants exhibited a significantly decreased egg-laying rate, albeit not as severe as the double mutant. The egg-laying neural circuit consists of two motor neurons, HSN and VC, which synapse onto the vulval muscles to cause muscle contraction and egg release [46]. Both neurons receive little synaptic input from other cells: VC neurons receive input from HSN and other VC neurons, while HSN neurons receive input from the VCs, two interneurons, and PLM, a body touch mechanosensory neuron [46]. Because flp-1 is not expressed in the egg-laying neural circuit, these results suggest that FLP-1 peptides act extra-synaptically to modulate the egg-laying neural circuit. Furthermore, because both loss and overexpression of FLP-1 peptides decrease egg-laying rates, either different FLP-1 peptides have different effects on the egg-laying circuit or high levels of FLP-1 peptides, as in the transgenic animals, cause activation of additional circuits to decrease egg laying.

**Conclusions**

Sensory neurons send signals to interneurons, which in turn signal to motor neurons, resulting in an animal responding to a change in the environment [47]. DAF-10 IFT-A activity in amphidial and phasmid sensory neurons is necessary for ciliogenesis and, therefore, sensory function. flp-1 is expressed in many interneurons [22], which serve to transmit information from the sensory neurons to the motor neurons. Hence, decreased DAF-10 IFT-A activity affects behaviors that are dependent on sensory information, such as osmolarity and nose touch responses, locomotion, and egg laying; with the exception of osmolarity, these sensory deficits are exacerbated when flp-1 signaling is lost in the interneurons. As FLP-1 peptides are not expressed in the egg-laying neural circuit, the FLP-1 peptides must be acting extra-synaptically to influence egg-laying rate. Furthermore, different FLP-1 peptides must be affecting egg-laying circuits differentially as both increased and decreased FLP-1 peptide levels result in decreased egg-laying rate. Determining the function of specific FLP-1 peptides awaits future studies.

The wandering behavior is the result of a synergistic effect of loss of both sensory function and downstream signaling through FLP-1 peptides. Wandering animals are able to chemotax to food, but wander off food within a few hours. Chemoattraction to food is dependent on amphidial neurons; however, loss of amphidial function in daf-10 mutants does not result in
wandering animals, suggesting that a different pathway that utilizes FLP-1 peptides to sense food is operating. Loss of both pathways results in wandering.

Supporting information

S1 File. Supporting material & methods. RNA was isolated from populations of wild type (N2), daf-10 flp-1(yn2), and flp-1(ok2811, ok2781, and ok2505) mutants with Trizol (Ambion) and reverse-transcribed with an oligo-dT primer according to the manufacturer’s protocol (Promega). Synthesized cDNA was amplified with MR23 (5’-CTGCAGATAACAAGTTTAC TTG) and D10-2 (5’-GACGTACTGTCACTGACCAAATCC) or with MR38 (5’-CGCACATT TGCATCAAGAG) and D10-2. Products were electrophoresed on an 0.8% agarose gel and visualized with a UV transilluminator (UVP gel-doc system).

(S1 Fig. Expression of daf-10 transcripts is not affected in flp-1(ok2811, ok2781, ok2505) mutants. RNA from wild type (WT), flp-1 single, and daf-10 flp-1(yn2) double mutants was isolated and reverse transcribed with an oligo-dT primer. The cDNA was amplified with two primer pairs, one set (MR23/D10-2) in which one primer is contained within the yn2 deletion, but not within the flp-1 single deletion mutations (756 bp, arrow), and one set (MR38/D10-2) in which the primers are not contained within the yn2 deletion or any flp-1 single deletions (283 bp, chevron). The larger products (722 bp) in the MR38/D10-2 amplification (red asterisks) were due to DNA contamination. M = molecular weight markers.)

Acknowledgments

We thank Piali Sengupta for the tax-4 mutant, the C. elegans Knockout Consortium for the flp-1 alleles, the Caenorhabditis Genetics Center for other strains, WormBase for some strain information, and Casey Brander for help with amplitude measurements. We thank past and present members of our laboratory for helpful discussions.
