Lipid microdomains

ABSTRACT

Lipid microdomains (‘lipid rafts’) are plasma membrane subregions, enriched in cholesterol and glycosphingolipids, which participate dynamically in cell signaling and molecular trafficking operations. One strategy for the study of the physicochemical properties of lipid rafts in model membrane systems has been the use of nuclear magnetic resonance (NMR), but until now this spectroscopic method has not been considered a clinically relevant tool. We performed a proof-of-concept study to test the feasibility of using NMR to study lipid rafts in human tissues. Platelets were selected as a cost-effective and minimally invasive model system in which lipid rafts have previously been studied using other approaches. Platelets were isolated from plasma of medication-free adult research participants (n = 13) and lysed with homogenization and sonication. Lipid-enriched fractions were obtained using a discontinuous sucrose gradient. Association of lipid fractions with GM1 ganglioside was tested using HRP-conjugated cholera toxin B subunit dot blot assays. 1H high resolution magic-angle spinning nuclear magnetic resonance (HRMAS NMR) spectra obtained with single-pulse Bloch decay experiments yielded spectral linewidths and intensities as a function of temperature. Rates of lipid lateral diffusion that reported on raft size were measured with a two-dimensional stimulated echo longitudinal encode-decode NMR experiment. We found that lipid fractions at 10–35% sucrose density associated with GM1 ganglioside, a marker for lipid rafts. NMR spectra of the membrane phospholipids featured a prominent ‘centerband’ peak associated with the hydrocarbon chain methylene resonance at 1.3 ppm; the linewidth (full width at half-maximum intensity) of this ‘centerband’ peak, together with the ratio of intensities between the centerband and ‘spinning sideband’ peaks, agreed well with values reported previously for lipid rafts in model membranes. Decreasing temperature produced decreases in the 1.3 ppm peak intensity and a discontinuity at ~18 °C, for which the simplest explanation is a phase transition from Ld to Lo phases indicative of raft formation. Rates of lateral diffusion of the acyl chain lipid signal at 1.3 ppm, a quantitative measure of microdomain size, were consistent with lipid molecules organized in rafts. These results show that HRMAS NMR can characterize lipid microdomains in human platelets, a methodological advance that could be extended to other tissues in which membrane biochemistry may have physiological and pathophysiological relevance.

1. Introduction

Lipidomics has wide implications for human health. Among the most fundamental roles for lipids is their participation in cell membranes, where they serve not only structural but also dynamic functions. Current understanding of cell membrane organization postulates the existence of lipid microdomains, or rafts, comprised principally of cholesterol and sphingolipids, which self-segregate from the surrounding phospholipid bilayer [1] due to sterically aversive forces [2]. The largely dietarily-determined lipid balance can affect the physicochemical properties of the membrane microdomains, with downstream effects on cell-cell signaling, molecular trafficking, and regulation of transmembrane proteins, including a variety of transporters and G-protein coupled receptors [3]. Among technologies used to study the composition of lipid rafts, 1H detected high-resolution magic-angle spinning nuclear magnetic resonance (HRMAS NMR) utilizes the

natural proton signals from lipids to provide very good resolution of chemically shifted resonances through rapid spinning of samples at the "magic angle" (54.7°) with respect to the main magnetic field. NMR has been used to characterize lipid rafts in model membrane systems [4–9,11–14], in cell culture [15–17], and in the influenza viral envelope [18]. However, NMR has not been utilized in clinical studies of human cell membranes. Therefore we proceeded to test the feasibility of using HRMAS NMR to characterize lipid rafts in human platelets, in which lipid rafts have been successfully studied using other methods [19–22]. The NMR approach allows for physicochemical characterization of lipid rafts at the molecular level. Potential applications include studies of the effects of dietary intake of lipids (e.g., polyunsaturated fatty acids and cholesterol) and antihyperlipidemic medications on cell membrane functioning in healthy individuals and in pathological states.

2. Materials and methods

2.1. Sample

Platelets were isolated from plasma of medication-free adult research participants (n = 13) with major depressive disorder who were otherwise medically healthy, and who had enrolled in mood disorders protocols at the New York State Psychiatric Institute and gave informed consent to the collection of blood samples for biochemical studies.

2.2. Purification of platelet lipid domains

Platelets were extracted from blood samples as previously described according to methods optimized by our research team [23]. Briefly, the blood was collected in EDTA vacutainer tubes and centrifuged at low speed to obtain the platelet-rich-plasma, which was then further centrifuged (12,000 × g, 4 ºC, 4 min). The resulting pellets were resuspended in 5 mL of ice-cold phosphate-buffered saline (PBS, pH 7.4) and again pelleted and stored at −80 ºC until used. For the next (homogenization) step, the platelet pellets were resuspended and washed twice in ice-cold PBS and suspended in 2 mL of 500 mM Na2CO3 solution, pH 11.0.

To avoid artifacts associated with detergent extraction [24,25], lipid rafts were isolated from extracted platelets using non-detergent methods: cells were lysed using a Polytron Homogenizer (Brinkmann, Lucerne, Switzerland; three 10-s bursts at setting 3) and then subjected to sonication with an XL-2000 Ultrasonic Cell Disruptor (Microson, Rockford, IL, USA) [26]. The supernatant was removed by centrifugation (10,000 rpm for 20 min); the pellets were saved and stored at −80 ºC.

Reconstituted in deuterated water (D2O). Five washes in D2O were each performed by adding 300 µL of deuterated water to each sample in a microcentrifuge tube, spinning the samples at 10,000 rpm for 15 min, and decanting the clear layer using a pipette. Between each wash, samples were frozen via direct contact of the outside of the microcentrifuge tube with dry ice and thawed at room temperature followed by gentle vortexing. These freeze-thaw cycles were performed in order to facilitate H/D exchange between the solvent and membrane fragments. Samples thus prepared for HRMAS NMR were slightly viscous and visibly, uniformly opaque suspensions of multilayers.

Butylated hydroxytoluene (BHT) was added to all samples to prevent oxidation of the unsaturated lipid acyl chains. Water-soluble 4,4-dimethyl-4-silapentane-1-sulfonic acid (DSS) was added to all samples at a ratio of 100:1 lipid:DSS by weight as a chemical shift calibration standard for NMR spectroscopy.

NMR data were acquired at the New York Structural Biology Center on a 4-channel Bruker Avance I widebore spectrometer equipped with a 4 mm HRMAS HCN probe and ZrO2 rotors (Bruker Biospin, Karlsruhe, Germany), operating at a 1H resonance frequency of 750 MHz and using a spectral width of 15 kHz. Samples were spun at an angle of 54.7° to the magnetic field direction (the ‘magic angle’) at spinning frequencies of 4–5 kHz to obtain well-resolved spectra. 1H spectra were acquired with a single-pulse Bloch decay experiment [30] using an 8 µs 90° pulse. We acquired 128 scans with a recycle delay of 2 s between data acquisitions, thus requiring ~4 min to obtain each spectrum. The signal-to-noise ratio for the main lipid resonance was 50:1, allowing for reliable estimates of peak intensity and linewidth at half height.

A presaturation water suppression technique was used to suppress the signal from residual 1H nuclei in the D2O solvent. Experiments were executed with and without a pre-acquisition echo sequence to test for the presence of broad signals [31]. Measurement temperatures were varied from −10 ºC to 35 ºC and calibrated with a methanol standard [32]. Sideband / centerband intensity ratios and linewidth differences of the principal lipid resonance at ~1.3 ppm were monitored vs. temperature, and these ratios were used to validate the presence of rafts in the Lp phase [13].

Rates of lipid lateral diffusion (signal intensity decay as a function of time) were measured in a two-dimensional stimulated echo longitudinal encode-decode experiment conducted with presaturation and bipolar gradients [33] (256 scans, gradient length 8 µs, recycle delay

2 s, gradient strengths of 2–96% in 32 steps (1 G/cm–48 G/cm), 1500 μs delay based on the length of the gradient pulse, diffusion time 100 ms).

3. Results

3.1. Purification of lipid microdomains

On sucrose gradient fractionation, a distinct opalescent band was visualized between 5% and 35% sucrose density, in fractions 3–5 (Fig. 1A), and the presence of lipid rafts was supported by GM1 ganglioside-positive dot blots in the same fractions (Fig. 1B). Chemiluminescence results (Fig. 1B) revealed that lipid fractions were positive for the presence of GM1 gangliosides, which have been associated with lipid raft domains [34]. The BCA assay was consistent with the presence of raft-associated and non-raft-associated proteins, in fractions 4 and 9, respectively (Fig. 1C).

3.2. Spectroscopic properties of purified platelet lipid fractions

As expected, the most prominent feature in the membrane phospholipid spectrum (Fig. 2) was the hydrocarbon chain ‘bulk’ methylene resonance at ~1.3 ppm. No broad spectral contributions were evident in data obtained without the pre-acquisition spin echo sequence, arguing against the presence of residual membrane-associated proteins or lipids in the S0 phase. Across the 4 platelet-derived lipid multibilayer samples, we observed linewidth values (full width at half-maximum intensity) for the ‘centerband’ methylene peak at 1.3 ppm ranging from 55 to 82 Hz at 6.5 °C, with corresponding sideband:centerbond ratios amounting to 2.5–5.3%. Compared with small-molecule standards such as DSS, the centerband peak thus exhibits a clearly broadened resonance. Nonetheless, these relatively modest centerband linewidths and sideband proportions, together with the similarity in magnitude of the linewidths for the (CH2)n centerband and sideband (shown in Fig. 2), are more characteristic of the liquid-ordered (Lo) phase identified with lipid rafts in equilibrium with a liquid-disordered (Ld) phase [6] than with a significant S0 component. Our findings are also consistent with reports of model membrane systems in which raft formation accompanied by enhanced membrane order has been associated with greater proportions of cholesterol with respect to phospholipid, producing a modestly broadened centerband peak and minor redistribution of the signal intensity from centerband to sidebands [4].

3.3. Phase transitions and raft formation demonstrated through 1H NMR spectra at varying temperatures

A temperature series (Fig. 3) provides information about the phase transition between the Ld and Lo phases of our lipid-enriched platelet preparation. Decreasing height of the 1.3-ppm peak in response to decreasing temperature (Fig. 3A), which is accompanied by an increase in peak linewidth, is most simply explained by an increased predominance of Lo relative to Ld phase of the membranes [5]. In a more quantitative presentation of the data (Fig. 3B), the intensity of the 1.3-ppm peak is illustrated as a function of temperature; a discontinuity is apparent at higher temperatures; extrapolation of the two straight-line portions yields an intersection point from which the apparent Ld to Lo phase transition temperature is estimated to be ~18 °C.

3.4. Diffusion as a measure of average domain size

The dependence of peak intensity on gradient strength is a measure of the translational diffusion constant. Diffusion is spatially restricted if the average distance that lipids move during the diffusion time is constant for a sufficiently long period. We extracted an order-of-magnitude diffusion constant of $1.4 \times 10^{-11}$ m$^2$/s, a measure of average
resembles that of Veatch et al. [5], except the platelet membrane data are shifted to the left. The 30:70 cholesterol:PC phospholipids model membranes exhibit a Lc-to-Ld transition temperature of ~32 °C for the binary lipid mixture [5], consistent with the presence of high-melting DPPC, in contrast to an apparent Lc-to-Ld transition temperature of ~18 °C for our more complex mixture that includes phospholipid species with unsaturated acyl chains. By comparison, Fourier transform infrared spectroscopy (FT-IR) methods show phase transitions at ~15 and ~30 °C for intact platelets prepared without lipid enrichment [36].

We acknowledge that the demonstration of phase transition is not proof that functional rafts exist in the extracted fractions. In the following section we discuss combining NMR studies with biological assays to verify the presence of rafts by assessing various functional characteristics.

4.1. Potential of NMR as a clinical tool to study lipid rafts in biological membranes

Because of their renewability, platelets can provide a cost-effective and minimally invasive ex vivo method for studying the functions of lipid rafts in humans. Standardized methods for obtaining a detailed platelet lipid raft profile could provide a platform for understanding whether lipid raft changes mediate effects on clinical symptoms. Such methods of valuation may eventually be useful for evaluating the risk of chronic conditions already associated with lipid rafts, including Parkinson’s disease [37], dementia [38], atherosclerosis [39,40], rheumatoid arthritis [41], and depression [42,43].

To approach this goal, lipid raft functional roles in cell signaling [44] and protein trafficking [45] could be studied using NMR measurement of lipid raft physicochemical properties accompanied by dynamic functional studies after perturbation or enhancement of lipid raft characteristics. For instance, lipid raft disruption by cholesterol depletion alters mobility of the serotonin transporter [46], decreases transport activity, and reduces transporter affinity for serotonin [47,48]. As another example, polyunsaturated fatty acids (PUFAs) have direct effects on the physicochemical properties of plasma membrane lipid subdomains in model membrane systems [2,7–9,11,12], and incorporation of polyunsaturated fatty acids into lipid rafts increases antibody binding to major histocompatibility complex (MHC) class I membrane proteins on certain cell types [49]. These structure-function studies have all been carried out in cell culture [46,48–50], heterologous expression systems [47] or animal models [47,50]. Our NMR technique, however, is designed to be used in studies of human platelets or other cell types. In combination with functional assays, NMR could thus be used to prospectively assess effects of dietary PUFA supplementation or cholesterol-lowering medications on activity of membrane proteins and how changes in activity relate to changes in raft structural properties.

4.2. Limitations

Potential limitations include artifacts induced by the sucrose gradient and mechanical disruption of membranes, and lack of information about the ganglioside and protein components of the system. We note that NMR spectra were monitored over a limited range of temperatures in this preliminary feasibility study. Additional studies encompassing a greater range of temperatures would be required in order to verify whether other discontinuities also occur.

5. Conclusions

Our findings introduce a novel translational application for a powerful basic science tool. NMR quantification of platelet lipid rafts can enhance other high-resolution and quantitative approaches [51,52] to the study of structural and functional characteristics of lipid microdomains. This new translational approach could have clinical utility for understanding physiology and pathophysiology at the
