Abstract

Fast Algorithms on Random Matrices
and Structured Matrices

by

Liang Zhao

Advisor: Victor Y. Pan

Randomization of matrix computations has become a hot research area in the big data era. Sampling with randomly generated matrices has enabled fast algorithms to perform well for some most fundamental problems of numerical algebra with probability close to 1. The dissertation develops a set of algorithms with random and structured matrices for the following applications:

1) We prove that using random sparse and structured sampling enables rank-\(r\) approximation of the average input matrix having numerical rank \(r\).

2) We prove that Gaussian elimination with no pivoting (GENP) is numerically safe for the average nonsingular and well-conditioned matrix pre-processed with a nonsingular and well-conditioned f-Circulant or another
structured multiplier. This can be an attractive alternative to the customary Gaussian elimination with partial pivoting (GEPP).

3) By using structured matrices of a large family we compress large-scale neural networks while retaining high accuracy. The results of our extensive are in good accordance with those of our theoretical study.

2.1 Matrices of Algorithm 2.6.1 49
Chapter 1

Introduction

Structured matrices (such as Toeplitz, Hankel, Vandermonde, and Cauchy matrices, see Table 1) are also called Data Sparse because such an $n \times n$ matrix can be represented with $O(n)$ parameters, that is, linear number in dimension $n$, rather than with $n^2$ entries.

Furthermore computations with such matrices require much fewer arithmetic operations than the same computations with general matrices. The most fundamental operations of matrix computations are multiplication of a matrix by a vector, multiplication of pairs of matrices, and the solution of a linear system of equations. When these operations are performed with general matrices, they require quadratic arithmetic time (for multiplication by a vector), or cubic time, but these bounds are decreased to nearly linear time in the case of structured matrices (see Table 1). This means dramatic saving of computer time and memory in modern large scale computations,
allowing to perform routinely computations that previously were unfeasible.

The intensive study in this field has produced efficient algorithms applied to various areas of computing, but this study is relatively recent, less than 50 years old, and for a while was mostly restricted to the important classes of Toeplitz and Hankel matrices, although already that study has involved

nontrivial mathematical tools.

It turned out that a much wider class of structured matrices is highly important. New progress requires more advanced mathematical techniques, and the class of highly important applications to modern computing is growing fast. Together with the number and sophistication of mathematical techniques involved, the current study of this subject is flourishing.

In this thesis, we present some sample applications of sparse and structured matrices to some fundamental and highly popular problems of modern computations, where we demonstrate the power of this approach, show some advanced technical tools, and variety of its applications to modern computations for sciences, engineering, signal and image processing, and data mining and analysis.

In particular application of sparse and structured matrices enables us to enhance the power of randomization which is another recent technique extensively applied in order to advance fundamental matrix computations.

1.1 Low Rank Approximation of a Matrix

Low-rank approximation of a matrix has a variety of applications to the most fundamental matrix computations [HMT11] and numerous problems of data mining and analysis, “ranging from term document data to DNA SNP data”
[M11]. Classical solution algorithms use SVD or rank-revealing factorization, but the alternative solution by means of random sampling is numerically reliable, robust, and computationally and conceptually simple and has become highly and increasingly popular in the last decade (see [HMT11], [M11], [GL13, Section 10.4.5], [CMMa] for surveys and ample bibliography). Random sampling with Gaussian multipliers is likely to produce low-rank approximation with a probability close to 1,\footnote{Here and hereafter we refer to “standard Gaussian random” variables just as “Gaussian”, and “likely” means “with a probability close to 1”.} but empirically the same algorithms work as efficiently with various random structured multipliers [HMT11, Sections 4.6 and 10.2].

Adequate formal support for this empirical evidence has been elusive so far, but based on our new insight we provide such a support, which opens new opportunities for enhancing the efficiency of this approach. Namely, an $n \times l$ Gaussian sampling is likely to yield rank-$r$ approximation to any $m \times n$ matrix having numerical rank $r$ if $l \geq r + 20$ [HMT11, Section 10.2], but by virtue of our dual theorem, sampling with any well-conditioned $n \times l$ multiplier of full rank $l$ (we call such multipliers promising) supports rank-$r$ approximation of the average $m \times n$ matrix having numerical rank $r$ if $l \geq r$ and if, in the spirit of the Central Limit Theorem, the average matrix is
defined under the Gaussian probability distribution.

Our result should embolden search for new multipliers, to be generated and applied to an input matrix at a substantially lower computational cost than the structured multipliers of [HMT11], and we propose new families of such multipliers and some policies of managing the unlikely failure of sampling with such multipliers in Sections 2.5 and 2.6. We consistently succeeded in our extensive numerical tests of our recipes for benchmark inputs from [HMT11] as well as inputs generated according to [H02, Section 28.3].

By applying similar techniques we obtain similar progress for Gaussian elimination with no pivoting, block Gaussian elimination, and Least Squares Regression in [PZ17], [PSZa], and [PZa]; by extending these techniques we dramatically accelerate low-rank approximation of the average matrix in [PSZb].

1.2 Deep Neural Network Model Compression

Neural networks, especially large-scale deep neural networks, have made remarkable success in various applications such as computer vision, natural language processing, etc. [11][16]. However, large-scale neural networks are both memory-intensive and computation-intensive, thereby posing severe chal-
CHAPTER 1. INTRODUCTION

lenges when deploying those large-scale neural network models on memory-constrained and energy-constrained embedded devices. Various techniques have been proposed in order to overcome these limitations, by means of reducing the size of large-scale (deep) neural networks, for example, connection pruning [8][7], low rank approximation [6][9], sparsity regularization [17][13] etc.,

**LDR Construction and LDR Neural Networks:** Among those efforts, *low displacement rank (LDR) construction* is a type of structure-imposing technique for network model reduction and computational complexity reduction. By regularizing the weight matrices of neural networks using the format of LDR matrices (when weight matrices are square) or the composition of multiple LDR matrices (when weight matrices are non-square), a *strong structure* is naturally imposed to the construction of neural networks. Since an LDR matrix typically requires $O(n)$ independent parameters and supports fast matrix operation algorithms [14], an immense space for network model and computational complexity reduction can be enabled. Pioneering work in this direction [3][15] applied LDR matrices of specific classes, such as circulant matrices and Toeplitz matrices, for weight representation. Other types of LDR matrices exist such as Cauchy matrices, Vandermonde matrices, etc., as shown in Figure 1.
Figure 1.1: Examples of commonly used LDR (structured) matrices, i.e., circulant, Cauchy, Toeplitz, Hankel, and Vandermonde matrices.

**Benefits of LDR Neural Networks:** Compared with other types of network compression approaches, the LDR construction shows several unique advantages. First, unlike heuristic weight-pruning methods [8][7] that produce irregular pruned networks, the LDR construction approach always guarantees the strong structure of the trained network, thereby avoiding large overhead of its storage space and computation time incurred by the complicated indexing process. Second, as a “train from scratch” technique, LDR construction does not need extra re-training, and hence eliminates the additional complexity to the training process. Third, the reduction in space complexity and computational complexity by using the structured weight matrices are significant. Different from other approaches to network compression that can only provide a heuristic compression factor, the LDR construction enables the model reduction and computational complexity reduction in Big-O complexity: The storage requirement is reduced from $O(n^2)$ to $O(n)$, and the computational complexity can be reduced from $O(n^2)$ to $O(n \log n)$ or $O(n \log^2 n)$ because of the existence of fast matrix-vector multiplication algorithm [14][2] for LDR matrices. For example, when applying structured matrices to the fully-connected layers of AlexNet using ImageNet dataset [5],
CHAPTER 1. INTRODUCTION

the storage requirement can be reduced by a factor of more than 4,000 while incurring only negligible degradation in overall accuracy [3].

Motivation of This Work: Because of its inherent structure-imposing characteristic, convenient re-training-free training process and unique capability of simultaneous Big-O complexity reduction in storage and computation, LDR construction is a promising approach to achieve high compression ratio and high speedup for a broad category of network models. However, since imposing the structure to weight matrices results in substantial reduction of weight storage from $O(n^2)$ to $O(n)$, cautious researchers need to know whether the neural networks with LDR construction, to which we refer as LDR neural networks, consistently yields similar accuracy compared to uncompressed networks. Although [3][15] have already shown that using LDR construction still results in the same accuracy or allows only its minor degradation on various datasets, such as ImageNet [5], CIFAR [10] etc., the theoretical analysis, which can provide the mathematically solid proofs that the LDR neural networks can converge to the same “effectiveness” as the uncompressed neural networks, is still very necessary in order to promote the wide application of LDR neural networks for emerging and larger-scale applications.

Technical Preview and Contributions: To achieve these goals we
provide solid theoretical foundation for the ability of LDR neural networks
to approximate an arbitrary continuous function, to estimate error bounds
for function approximation, and to elaborate upon applications on shallow
and deep neural networks, etc. More specifically, the main contributions of
this chapter include:

- We prove the universal approximation property for LDR neural net-
  works, which states that the LDR neural networks can approximate
  an arbitrary continuous function with arbitrary accuracy given enough
  parameters/neurons. In other words, the LDR neural network has the
  same “effectiveness” as the classical neural networks that work without
  compression. This property serves as the theoretical foundation of the
  potential broad applications of LDR neural networks.

- We show that, for LDR matrices defined by $O(n)$ parameters, the corre-
  sponding LDR neural networks are still capable of achieving integrated
  squared error of order $O(1/n)$, which is identical to the error bound of
  neural networks based on unstructured weight matrices. Thus there is
  essentially no loss for restricting to the weight matrices to LDR matri-
  ces.

- We develop a universal training process for LDR neural networks with
computational complexity reduction compared with backward propagation process for classical neural networks. The proposed algorithm is the generalization of the training process in [3][15] that restricts the structure of weight matrices to circulant matrices or Toeplitz matrices.

1.3 Gaussian Elimination without Pivoting

The history of Gaussian elimination can be traced back some 2000 years [G11]. Its modern version, called Gaussian elimination with partial pivoting (hereafter we use the acronym GEPP), is performed routinely, millions times per day around the world, being a cornerstone for computations in linear algebra. For some samples of extensive and intensive applications of GEPP to Sciences, Technology, and Signal and Image Processing, the survey [DDF14] refers to fusion reactor modeling, aircraft design, acoustic scattering, antenna design, and radar cross-section studies and then recalls that, e.g., in simulating fusion reactors, GEPP is applied to solving dense linear systems of equations with over half a million unknowns.

For an $n \times n$ input matrix, partial pivoting, that is, row interchange, involves only $(n-1)n/2$ comparisons, versus about $\frac{3}{2}n^3$ arithmetic operations involved into elimination. Progress in computer technology, however, has made partial pivoting the bottleneck of Gaussian elimination. Here is a
relevant citation from [BCD14]: “The traditional metric for the efficiency of a numerical algorithm has been the number of arithmetic operations it performs. Technological trends have long been reducing the time to perform an arithmetic operation, so it is no longer the bottleneck in many algorithms; rather, communication, or moving data, is the bottleneck.”

Pivoting is communication intensive and in modern computer environment takes quite a heavy toll: it interrupts the stream of arithmetic operations with foreign operations of comparison, involves book-keeping, compromises data locality, impedes parallelization of the computations, and increases communication overhead and data dependence.

According to [BDHT13], “pivoting can represent more than 40% of the global factorization time for small matrices, and although the overhead decreases with the size of the matrix, it still represents 17% for a matrix of size 10,000”. Because of the heavy use of GEPP, even its limited improvement is valuable.

_Gaussian elimination with no pivoting_ (hereafter we keep using the acronym \textit{GENP}) is an attractive alternative to the customary GEPP, but it can fail or produce a corrupted output more readily than GEPP. To specify this, call an input matrix _unsafe and numerically unsafe_ for Gaussian elimination with or without pivoting if this algorithm applied to that matrix runs into a division
by 0 or into numerical problems, respectively. A singular input matrix is unsafe for both GENP and GEPP, and an ill-conditioned matrix is numerically unsafe for both of them (see the end of Section ?? on the concepts of ill- and well-conditioned matrices). Nonsingular matrices are safe for GEPP, and a very small fraction of them is unsafe for GENP. The matrices of only a small subclass of nonsingular and well-conditioned matrices are numerically unsafe for GENP, and even more rarely they are numerically unsafe for GEPP.

Since [W61], numerical safety or stability of Gaussian elimination has been tied to the growth factor \( \rho = \max_{i,j} |u_{ij}| / \max_{i,j} |a_{ij}| \) in the PLUP’ factorization (with or without pivoting) of a matrix \( A = (a_{ij})_{i,j} = PLUP' \) where \( L = (l_{ij})_{i,j} \) and \( U = (u_{ij})_{i,j} \) are lower and upper triangular factors, respectively, and \( P \) and \( P' \) are permutation matrices. In the case of GENP, both of \( P \) and \( P' \) turn into the identity matrix, \( P = P' = I_n \). In the case of GEPP, \( P' = I_n \), and we can choose any permutation matrix \( P \), defining row interchange. Both \( P \) and \( P' \) are our unrestricted choice in Gaussian elimination with complete pivoting, hereafter referred to as GECP, that is, in GECP we can interchange any pair of rows and columns.

For the worst case input, \( \rho \) is unbounded in the case of GENP, is as large as \( 2^{n-1} \) in the case of GEPP, and is in \( O(n^{(1+\log(\sqrt{n}))/2}) \) in the case of GECP. Nevertheless GEPP has been universally preferred by the user in most cases.
Its average growth factor is only $n^{2/3}$, which is just slightly larger than $n^{1/2}$ for GECP, and its pivoting is simpler than that of GECP, whereas GENP is considered numerically unsafe in practice and is little used, even though its average growth factor is just $n^{3/2}$, that is, only marginally larger than in the case of GEPP (cf. [TS90], [YC97]).

Block matrix algorithms are highly important resource for enhancing the efficiency of matrix algorithms [GL13], but block Gaussian elimination (hereafter we keep using the acronym BGE) is impeded because pivoting cannot helps us to avoid numerical stability problems for this algorithm. We can see in Section 4.1, however, that BCG is safe (resp., numerically safe) for any input matrix for which GENP is safe (resp., numerically safe). Thus we have yet another major motivation for studying GENP.

### 1.3.1 Preprocessing versus pivoting

Preprocessing $A \rightarrow FA$, $A \rightarrow AH$, and $A \rightarrow FAH$, for nonsingular matrices $F$ and $H$, is a natural resource for supporting GENP and BGE because $A^{-1} = (FA)^{-1}F$, $A^{-1} = G(AG)^{-1}$, and $A^{-1} = G(FAG)^{-1}F$ and because empirically the matrices $FA$, $AH$, and $FAH$ tend to be safe and numerically safe for GENP and BGE when the matrix $A$ is nonsingular and well-conditioned and when the matrices $F$ and $H$ are random. The above observations and
empirical data have recently convinced some leading experts in numerical matrix computations to implement GENP with randomized preprocessing (see [BBD12], [BDHT13], [BBBDD14], and [BLR15]). The resulting algorithm noticeably improves GEPP, even though preprocessing in the cited papers relies on the ad hoc multipliers from unpublished Technical Reports of 1995 by Parker and by Parker and Pierce. This leaves us with the challenge of finding even more efficient multipliers and preprocessing policies.

In this chapter we reexamine the state of the art, the role of randomization, and the benefits of using sparse and structured multipliers. We supply formal probabilistic analysis based on our nonstandard and more general techniques of analysis. Our techniques are much simpler (the proof of our basic Theorem 4.2.2 occupies just ten lines), but much more general. Our results are consistent with the ones based on estimating the growth factor of LU factorization, but unlike them cover BGE as well and are extended readily to the study of alternative methods of preprocessing of Gaussian elimination by means of augmentation and additive preprocessing as well as to the study of the highly important algorithms for low-rank approximation of a matrix.

We provide some new insights into the subject and new recipes for preprocessing such as incomplete GENP and BGE in Remark 4.2.2 and testing multipliers by action, successively or concurrently in Section 4.2.4. We spec-
ify some useful concepts (such as strongly well-conditioned matrices in Section 4.2.1, universal and random universal sets of multipliers in the abstract and Section 4.2.4, primal and dual randomization in Section 4.2.4, the dilemmas of random versus fixed preprocessing in Section 4.2.4 and of random versus fixed sampling in Section 2.4.3, and subcirculant multipliers in Remark C.0.3.

We also point out some promising basic choices of multipliers and their combinations in Section 4.3. Some of the basic choices are new, some go back to the 1990s (c.f. [BP94, Section 2.13], entitled “Regularization of a Matrix via Preconditioning with Randomization”) or extend our more recent study of randomized matrix algorithms, including GENP and BGE with preprocessing (cf. [PGMQ, Section 12.2], [PIMR10], [PQ10], [PQ12], [PQY14], [PQY15], and [PQZ13]).

1.3.2 Extensions of our study and its empirical support

All our results and recipes for GENP also apply to BGE. In Section 4.2.3 we point out a sample amelioration of GENP and BGE. In Section ?? we show that our alternatives of randomized augmentation and additive preprocessing imply some benefits for solving linear systems of equations by means of randomized GENP, BGE, and other methods.

In Section 2.4.3 we follow the lead of [PQY15] and extend our study
CHAPTER 1. INTRODUCTION

of GENP and BGE to low-rank approximation of a matrix by means of random sampling. This highly popular subject has been studied intensively and successfully in the last decade. Application areas include some of the most fundamental matrix computations [HMT11] as well as “data analysis, ranging from term document data to DNA SNP data” [M11]. We refer the reader to [HMT11], [M11], and [GL13, Section 10.4.5] for surveys and ample bibliography, and to [GZT97], [GTZ97], [T00], [FKV98/04], and [DKM06] for sample early works. Technical similarity of this approach to preprocessing for GENP and BGE (apparently never observed until [PQY15]) enables us to provide new insights into this subject and some novel recipes. We also discuss the related topic of low-rank representation of a matrix.

The results of our formal analysis are in good accordance with the data from our tests, presented in Section 4.5. In particular GENP with our new preprocessing (unlike the case of the known ones in [BDHT13] and [BBBDD14]) produced accurate outputs even with no iterative refinement.
Chapter 2

Low-rank Approximation: New Insights

2.1 Some Basic Definitions

- Typically we use the concepts “large”, “small”, “near”, “close”, “approximate”, “ill-conditioned” and “well-conditioned” quantified in the context, but we specify them quantitatively as needed.

- Hereafter “≪” means “much less than”; “flop” stands for “floating point arithmetic operation”.

- $I_s$ is the $s \times s$ identity matrix. $O_{k,l}$ is the $k \times l$ matrix filled with zeros.
- $\mathbf{0}$ is a vector filled with zeros.

- $(B_1 | B_2 | \ldots | B_h)$ denotes a $1 \times h$ block matrix with $h$ blocks $B_1, B_2, \ldots, B_h$. 
CHAPTER 2. LOW-RANK APPROXIMATION: NEW INSIGHTS

• \( \text{diag}(B_1, B_2, \ldots, B_h) \) denotes a \( h \times h \) block diagonal matrix with \( h \) diagonal blocks \( B_1, B_2, \ldots, B_h \).

• \( \text{rank}(W) \), \( \text{nrank}(W) \), and \( ||W|| \) denote the rank, the numerical rank, and the spectral norm of a matrix \( W \), respectively. \( ||W||_F \) denotes its Frobenius norm.

• \( W^T \) and \( WH \) denote its transpose and Hermitian transpose, respectively.

• An \( m \times n \) matrix \( W \) is unitary (in the real case also orthogonal) if \( WHW = I_n \) or if \( WW^H = I_m \).

• \( W = S_{W,\rho} \Sigma_{W,\rho} T_{W,\rho}^T \) is compact SVD of a matrix \( W \) of rank \( \rho \) with the unitary matrices of its singular vectors \( S_{W,\rho} \) and \( T_{W,\rho} \) and the diagonal matrix \( \Sigma_{W,\rho} = \text{diag}(\sigma_j(W))_{j=1}^\rho \) of its singular values.

• \( W^+ = T_{W,\rho} \Sigma_{W,\rho}^{-1} S_{W,\rho}^T \) is it Moore-Penrose pseudo inverse. [Recall that \( ||W^+|| = \frac{1}{\sigma_\rho(W)} \).]

• \( \kappa(W) = \sigma_1(W)/\sigma_\rho(W) = ||W|| \ ||W^+|| \geq 1 \) denotes the condition number of a matrix \( W \). A matrix is called ill-conditioned if its condition number is large in context and is called well-conditioned if this number \( \kappa(W) \) is reasonably bounded.
2.2 Randomized Matrix Computations (Definitions, Basic Results)

- The acronym “i.i.d.” stands for “independent identically distributed”, and we refer to “standard Gaussian random” variables just as “Gaussian”.

- We call an $m \times n$ matrix Gaussian and denote it $G_{m,n}$ if all its entries are i.i.d. Gaussian variables.

- $G^{m \times n}$, $\mathbb{R}^{m \times n}$, and $\mathbb{C}^{m \times n}$ denote the classes of $m \times n$ Gaussian, real, or complex matrices, respectively.

- $G_{m,n,r}$, $\mathbb{R}_{m,n,r}$, and $\mathbb{C}_{m,n,r}$, for $1 \leq r \leq \min\{m,n\}$, denote the classes of $m \times n$ matrices $M = UV$ (of rank at most $r$) where $U \in \mathbb{C}^{m \times r}$ and $V \in \mathbb{C}^{r \times n}$ are Gaussian, real, and complex, respectively.

- If $U \in G^{m \times r}$ and $V \in G^{r \times n}$, then we call $M = UV$ an $m \times n$ factor-Gaussian matrix of expected rank $r$. (In this case the matrices $U$, $V$ and $M$ have rank $r$ with probability 1 by virtue of Theorem A.1.1.)

Next we recall some basic results for randomized matrix computations (see proofs in [PSZa, Section 3]).
Theorem 2.2.1. Suppose that $A$ is an $m \times n$ matrix of full rank $k = \min\{m, n\}$, $F$ and $H$ are $r \times m$ and $n \times r$ matrices, respectively, for $r \leq k$, and the entries of these two matrices are non-constant linear combinations of finitely many i.i.d. random variables $v_1, \ldots, v_h$.

Then the matrices $F$, $FA$, $H$, and $AH$ have full rank $r$

(i) with probability 1 if $v_1, \ldots, v_h$ are Gaussian variables and

(ii) with a probability at least $1 - r/|S|$ if they are random variables sampled under the uniform probability distribution from a finite set $S$ having cardinality $|S|$.

Lemma 2.2.1. (Orthogonal invariance of a Gaussian matrix.) Suppose that $k$, $m$, and $n$ are three positive integers, $k \geq \min\{m, n\}$, $G$ is an $m \times n$ Gaussian matrix, and $S$ and $T$ are $k \times m$ and $n \times k$ orthogonal matrices, respectively. Then $SG$ and $GT$ are Gaussian matrices.

We state the following estimates for real matrices, but similar estimates in the case of complex matrices can be found, e.g., in [CD05]:

Definition 2.2.1. Norms of random matrices and expected value of a random variable. Write $\nu_{m,n} = ||G||$, $\nu_{m,n}^+ = ||G^+||$, and $\nu_{m,n,F}^+ = ||G^+||_F$, for a Gaussian $m \times n$ matrix $G$, and write $\mathbb{E}(v)$ for the expected value of a random variable $v$. ($\nu_{m,n} = \nu_{n,m}$, $\nu_{m,n}^+ = \nu_{n,m}^+$, and $\nu_{F,m,n} = \nu_{F,n,m}$, for all pairs of $m$
CHAPTER 2. LOW-RANK APPROXIMATION: NEW INSIGHTS

and \( n \).

**Theorem 2.2.2.** Suppose that \( m \) and \( n \) are positive integers, \( t \geq 0 \), and \( h = \max\{m, n\} \). Then

(i) Probability \( \{ \nu_{m,n} > t + \sqrt{m} + \sqrt{n} \} \leq \exp(-t^2/2) \) and

(ii) \( \mathbb{E}(\nu_{m,n}) \leq \sqrt{m} + \sqrt{n} \).

**Theorem 2.2.3.** Let \( \Gamma(x) = \int_0^\infty \exp(-t)t^{x-1}dt \) denote the Gamma function and let \( x > 0 \). Then

(i) Probability \( \{ \nu_{m,n}^+ \geq m/x^2 \} < \frac{x^{m-n+1}}{\Gamma(m-n+2)} \) for \( m \geq n \geq 2 \),

(ii) Probability \( \{ \nu_{n,n}^+ \geq x \} \leq 2.35\sqrt{n}/x \) for \( n \geq 2 \),

(iii) \( \mathbb{E}(\nu_{m,n}^+) \leq e^{\sqrt{m}/|m-n|} \), provided that \( m \neq n \) and \( e = 2.71828 \ldots \).

The probabilistic upper bounds of Theorem A.2.2 on \( \nu_{m,n}^+ \) are reasonable already in the case of square matrices, that is, where \( m = n \), but are strengthened very fast as the difference \( |m - n| \) grows from 1. Theorems A.2.1 and A.2.2 combined imply that an \( m \times n \) Gaussian matrix is well-conditioned unless the integer \( m + n \) is large or the integer \( |m - n| \) is close to 0. With some grain of salt we can still consider such a matrix well-conditioned even where the integer \( |m - n| \) is small or vanishes provided that the integer \( m \) is not large.
2.3 The Basic Algorithm, Primal and Dual Support

A matrix $M$ can be represented (respectively, approximated) by a product $UV$ of two matrices $U \in \mathbb{C}^{m \times r}$ and $V \in \mathbb{C}^{r \times n}$ if and only if $r \geq \text{rank}(M)$ (respectively, $r \geq n\text{rank}(M)$), and our goal is the computation of such a representation or approximation.

We rely on the following basic algorithm. for the fixed rank problem where we assume that we are given $r = n\text{rank}(M)$ or $r = \text{rank}(M)$. Otherwise we could have computed it by means of binary search based on recursive application of the algorithm or proceeded as in our Algorithm 2.6.1 of Section 2.6.2.

Algorithm 2.3.1. Range Finder (See [HMT11, Algorithms 4.1 and 4.2]).

**INPUT:** An $m \times n$ matrix $M$, a tolerance $\tau \geq 0$, and $r = n\text{rank}(M)$ such that $0 < r \ll \min\{m, n\}$.

**INITIALIZATION:** Fix an integer $l$ such that $r \leq l \ll \min\{m, n\}$ and an $n \times l$ matrix $B$.

**COMPUTATIONS:** 1. Compute the $m \times l$ matrix $MB$. Remove its columns that have small norms.
2. Orthogonalize its remaining columns (cf. [GL13, Theorem 5.2.3]),
   compute and output the resulting $m \times \bar{l}$ matrix $U = U(MB)$ where $\bar{l} \leq l$.

3. Estimate the error norm $\Delta = ||\tilde{M} - M||$ for $\tilde{M} = UU^T M$.
   
   If $\Delta \leq \tau$, output SUCCESS; otherwise FAILURE.

We call a pair of matrices $[M; B]$ hard for Algorithm 2.3.1 if the algorithm fails for that pair. For any fixed $B_0$ and any fixed $M_0$ we can readily define hard pairs $[M; B_0]$ and $[M_0; B]$, but next we prove that such pairs $[M; B_0]$ and $[M_0; B]$ are unlikely to be hard for Algorithm 2.3.1 if $M$ and $B$ are Gaussian matrices.

**Theorem 2.3.1.** Let Algorithm 2.3.1 be applied with a Gaussian multiplier $B \in \mathcal{G}^{n \times l}$. Then

(i) $\tilde{M} = M$ with probability 1 if $l \geq r = \text{rank}(M)$ (cf. Theorem 2.4.1)

and

(ii) it is likely that $\tilde{M} \approx M$ if $n \text{rank}(M) = r \leq l$, and the probability that $\tilde{M} \approx M$ approaches 1 fast as $l$ increases from $r + 1$ (cf. Theorem 4.4.1).

An $n \times l$ Gaussian matrix $B$ is defined by its $nl$ random entries, and can be pre-multiplied by a vector in $(2n - 1)l$ flops, but an $n \times l$ structured
matrix $B$ of subsample random Fourier or Hadamard transform\footnote{Hereafter we use the acronyms SRFT and SRHT.} is defined by $n + l$ random variables and can be pre-multiplied by a vector by using $O(n \log(l))$ flops (see [HMT11, Sections 4.6 and 11], [M11, Section 3.1], and [T11]). SRFT and SRHT multipliers $B$ are universal, like Gaussian ones: Algorithm 2.3.1 applied with such a multiplier is likely to approximate closely a matrix $M$ having numerical rank at most $r$, although the estimated failure probability $3 \exp(-p)$, for $p = l - r \geq 4$ with Gaussian multipliers increases to order of $1/l$ in the case of SRFT and SRHT multipliers (cf. [HMT11, Theorems 10.9 and 11.1], [M11, Section 5.3.2], and [T11]).

Empirically Algorithm 2.3.1 with SRFT and SRHT multipliers fails very rarely even for $l = r + 20$, although for some special input matrices $M$ it is likely to fail if $l = o(r \log(r))$ (cf. [HMT11, Remark 11.2] or [M11, Section 5.3.2]). Researchers have consistently observed similar empirical behavior with various other multipliers (see [HMT11], [M11], [W14], [PQY15], and the references therein), but so far no adequate formal support for that empirical observation has appeared in the huge bibliography on this highly popular subject. Our Dual Theorem 2.3.2 below, however, provides such a formal support. The theorem reverses the assumptions of our Primal Theorem 4.2.1 that a multiplier $B$ is Gaussian, while a matrix $M$ is fixed.
Theorem 2.3.2. Let $M - E \in G_{m,n,r}$ and $\|E\|_2 \approx 0$ (in which case we have $\text{nrank}(M) \leq r$ and, with a probability close to 1, $\text{nrank}(M) = r$). Furthermore let $B \in \mathbb{R}^{n \times l}$ and $\text{nrank}(B) = l$. Then

(i) Algorithm 2.3.1 outputs a rank-$r$ representation of a matrix $M$ with probability 1 if $E = 0$ and if $l = r$ (cf. Theorem 2.4.1), and

(ii) it outputs a rank-$l$ approximation of that matrix with a probability close to 1 if $l \geq r$ and approaching 1 fast as the integer $l$ increases from $r + 1$ (cf. Theorem 2.4.4).

Claim (ii) implies that Algorithm 2.3.1 succeeds for the average input matrix $M$ that has a small numerical rank $r \leq l$ (and thus in a sense to most of such matrices) if the multiplier $B$ is a well-conditioned matrix of full rank and if the average matrix is defined under the Gaussian probability distribution. The former provision, that $\text{nrank}(B) = l$, is natural for otherwise we could have replaced the multiplier $B$ by an $n \times l_-$ matrix for some integer $l_- < l$. The latter provision is customary in view of the Central Limit Theorem.

2.4 Proof of the Primal and Dual Theorems

2.4.1 Computation of low-rank representation: proof

Hereafter $\mathcal{R}(W)$ denotes the range of $W$. Our next theorem implies claims (i) of Theorems 4.2.1 and 2.3.2.
CHAPTER 2. LOW-RANK APPROXIMATION: NEW INSIGHTS

Theorem 2.4.1. (i) For an \( m \times n \) input matrix \( M \) of rank \( r \leq n \leq m \), its rank-\( r \) representation is given by the products \( R(R^TR)^{-1}R^TM = U(R)U(R)^TM \) provided that \( R \) is an \( n \times r \) matrix such that \( \mathcal{R}(R) = \mathcal{R}(M) \) and that \( U(R) \) is a matrix obtained by means of column orthogonalization of \( R \).

(ii) \( \mathcal{R}(R) = \mathcal{R}(M) \), for \( R = MB \) and an \( n \times r \) matrix \( B \), with probability 1 if \( B \) is Gaussian, and

(iii) with a probability at least \( 1 - r/|S| \) if an \( n \times r \) matrix \( B \) has i.i.d. random entries sampled uniformly from a finite set \( S \) of cardinality \( |S| \).

Proof. Readily verify claim (i) (cf. [S98, pages 60–61]). Then note that \( \mathcal{R}(MB) \subseteq \mathcal{R}(M) \), for an \( n \times r \) multiplier \( B \). Hence \( \mathcal{R}(MB) = \mathcal{R}(M) \) if and only if rank\((MB) = r \), and therefore if and only if a multiplier \( B \) has full rank \( r \). Now claims (ii) and (iii) follow from Theorem A.1.1.

2.4.2 Analysis of low-rank approximation: a basic step

In our proofs of Theorems 2.6.1, 4.2.1, and 2.3.2 we rely on the following lemma and theorem.

Lemma 2.4.1. (Cf. [GL13, Theorem 2.4.8].) For an integer \( r \) and an \( m \times n \) matrix \( M \) where \( m \geq n > r > 0 \), set to 0 the singular values \( \sigma_j(M) \), for \( j > r \), let \( M_r \) denote the resulting matrix, which is a closest rank-\( r \) approximation
CHAPTER 2. LOW-RANK APPROXIMATION: NEW INSIGHTS

of $M$, and write $M = M_r + E$. Then

$$||E|| = \sigma_{r+1}(M) \quad \text{and} \quad ||E||_F^2 = \sum_{j=r+1}^{n} \sigma_j^2 \leq \sigma_{r+1}(M)^2(n-r).$$

**Theorem 2.4.2.** The error norm in terms of $||(M_rB)^+||$. Assume dealing with the matrices $M$ and $\tilde{M}$ of Algorithm 2.3.1, $M_r$ and $E$ of Lemma 2.4.1, and $B \in \mathbb{C}^{n \times l}$ of rank $l$. Let $\text{rank}(M_rB) = r$ and write $E' = EB$ and $\Delta = ||\tilde{M} - M||$. Then

$$||E'||_F \leq ||B||_F \quad ||E||_F \leq ||B||_F \sigma_{r+1}(M) \sqrt{n-r},$$

$$|\Delta - \sigma_{r+1}(M)| \leq \sqrt{8} \quad ||(M_rB)^+|| \quad ||E'||_F + O(||E'||_F^2).$$

**Proof.** Lemma 2.4.1 implies bound (2.4.1).

Next apply claim (i) of Theorem 2.4.1 for matrix $M_r$ replacing $M$, recall that $\text{rank}(M_rB) = l$, and obtain

$$U(M_rB)U(M_rB)^T M_r = M_r, \quad \mathcal{R}(U(M_rB)) = \mathcal{R}(M_rB) = \mathcal{R}(M_r).$$

Furthermore $U(M_rB)^T(M - M_r) = O_{n,n}$. Hence $U(M_rB)U(M_rB)^T M = U(M_rB)U(M_rB)^T M_r = M_r$.

Consequently, $M - U(M_rB)U(M_rB)^T M = M - M_r = E$, and so (cf. Lemma 2.4.1)

$$||M - U(M_rB)U(M_rB)^T M|| = \sigma_{r+1}(M).$$

(2.4.3)
Apply [PQY15, Corollary C.1], for $A = M_r B$ and $E$ replaced by $E' = (M - M_r) B$, and obtain

\[ \|U(MB)U(MB)^T - U(M_r B)U(M_r B)^T\| \leq \sqrt{8}(||M_r B||_F + O(||E'||_F^2)). \]

(2.4.4)

Combine this bound with (2.4.3) and obtain (2.4.2).

By combining bounds (2.4.1) and (2.4.2) obtain

\[ |\Delta - \sigma_{r+1}(M)| \leq \sqrt{8(n-r)} \sigma_{r+1}(M) ||B||_F ||(M_r B)^+|| + O(\sigma_{r+1}^2(M)). \]

(2.4.5)

In our applications the value $\sqrt{8(n-r)} \sigma_{r+1}(M)||B||_F$ is small, and so the value $|\Delta - \sigma_{r+1}(M)|$ is small unless the norm $||(M_r B)^+||$ is large.

2.4.3 Detailed estimates for primal and dual low-rank approximation

The following theorem, proven in the next subsection, bounds the approximation errors and the probability of success of Algorithm 2.3.1 for $B \in G^{n \times l}$.

Together these bounds imply claim (ii) of Theorem 4.2.1.

**Theorem 2.4.3.** Suppose that Algorithm 2.3.1 has been applied to an $m \times n$ matrix $M$ having numerical rank $r$ and that the multiplier $B$ is an $n \times l$ Gaussian matrix.
(i) Then the algorithm outputs an approximation $\tilde{M}$ of a matrix $M$ by a rank-$l$ matrix within the error norm bound $\Delta$ such that $|\Delta - \sigma_{r+1}(M)| \leq f_{d}\sigma_{r+1}(M)/\sigma_r(M) + O(\sigma^2_{r+1}(M))$ where $f = \sqrt{8(n-r)} \nu_{F,n,l}^+ \nu_{r,l}^+$ and $\nu_{F,n,l}$ and $\nu_{r,l}^+$ are random variables of Definition 2.2.1.

(ii) $E(f) < (1 + \sqrt{n} + \sqrt{l})e^2\sqrt{8(n-r)rl}$, for $p = l - r > 0$ and $e = 2.71828\ldots$.

**Remark 2.4.1.** $\sigma_{r+1}(M)$ is the optimal upper bound on the norm $\Delta$, and the expected value $E(f)$ is reasonably small even for $p = 1$. If $p = 0$, then $E(f)$ is not defined, but the random variable $\Delta$ estimated in Theorem 4.4.1 is still likely to be reasonably close to $\sigma_{r+1}(M)$ (cf. claim (ii) of Theorem A.2.2).

In Section 2.4.5 we prove the following elaboration upon dual Theorem 2.3.2.

**Theorem 2.4.4.** Suppose that Algorithm 2.3.1, applied to a small-norm perturbation of an $m \times n$ factor-Gaussian matrix with expected rank $r < m$, uses an $n \times l$ multiplier $B$ such that $\text{rank}(B) = l$ and $l \geq r$.

(i) Then the algorithm outputs a rank-$l$ matrix $\tilde{M}$ that approximates the matrix $M$ within the error norm bound $\Delta$ such that $|\Delta - \sigma_{r+1}(M)| \leq f_{d}\sigma_{r+1}(M) + O(\sigma^2_{r+1}(M))$, where $f_{d} = \sqrt{8(n-r)}l \nu_{r,l}^+ \nu_{m,r}^+ \kappa(B)$, $\kappa(B) =$...
\(| |B|| \ | |B^{+}\|\), and \(\nu_{m,r}^{+}\) and \(\nu_{r,l}^{+}\) are random variables of Definition 2.2.1.

\[(ii) \quad \mathbb{E}(f_d) < e^2 \sqrt{8(n-r)l \kappa(B)(m-r)^p}, \quad \text{for } p = l - r > 0 \text{ and } e = 2.71828\ldots \]

**Remark 2.4.2.** The expected value \(\mathbb{E}(\nu_{m,r}^{+}) = \frac{\sqrt{r}}{m-r}\) converges to 0 as \(m \to \infty\) provided that \(r \ll m\). Consequently the expected value \(\mathbb{E}(\Delta) = \sigma_{r+1}(\mathbf{M})\mathbb{E}(f_d)\) converges to the optimal value \(\sigma_{r+1}(\mathbf{M})\) as \(\frac{m}{r\sqrt{nl}} \to \infty\) provided that \(B\) is a well-conditioned matrix of full rank and that \(1 \leq r < l \ll n \leq m\).

**Remark 2.4.3.** [HMT11, Theorem 10.8] also estimates the norm \(\Delta\), but our estimate in Theorem 4.4.1, in terms of random variables \(\nu_{F,n,l}\) and \(\nu_{r,l}^{+}\), is more compact, and our proof is distinct and shorter than one in [HMT11], which involves the proofs of [HMT11, Theorems 9.1, 10.4 and 10.6].

**Remark 2.4.4.** By virtue of Theorems A.1.1, \(\operatorname{rank}(M_rB) = r\) with probability 1 if the matrix \(B\) or \(M\) is Gaussian, (as in Theorems 4.4.1 and 2.4.4), and we deduced (2.4.5) from the equation \(\operatorname{rank}(M_rB) = r\).

**Remark 2.4.5.** The Power Scheme of increasing the output accuracy of Algorithm 2.3.1. See [RST09], [HMST11]. Define the Power Iterations \(M_i = (M^T M)^i M\), \(i = 1, 2, \ldots\) Then \(\sigma_j(M_i) = (\sigma_j(M))^{2i+1}\) for all \(i\) and \(j\) [HMT11, equation (4.5)]. Therefore, at a reasonable computational cost,
one can dramatically decrease the ratio $\frac{\sigma_{r+1}(M)}{\sigma_r(M)}$ and thus decrease the bounds of Theorems 4.4.1 and 2.4.4 accordingly.

In the next two subsections we deduce reasonable bounds on the norm $||(M_rB)^+||$ in both cases where $M$ is a fixed matrix and $B$ is a Gaussian matrix and where $B$ is fixed matrix and $M$ is a factor Gaussian matrix (cf. Theorems 2.4.5 and 2.4.6). The bounds imply Theorems 4.4.1 and 2.4.4.

### 2.4.4 Primal theorem: completion of the proof

**Theorem 2.4.5.** For $M \in \mathbb{R}^{m \times n}$, $B \in \mathcal{G}^{m \times l}$, and $\nu_{r,l}^+$ of Definition 2.2.1, it holds that

$$||(M_rB)^+|| \leq \frac{\nu_{r,l}^+}{\sigma_r(M)}.$$  

(2.4.6)

**Proof.** Let $M_r = S_r \Sigma_r T_r^T$ be compact SVD. By applying Lemma A.2.1, deduce that $T_r^T B$ is a $r \times l$ Gaussian matrix. Denote it $G_{r,l}$ and obtain

$$M_r B = S_r \Sigma_r T_r^T B = S_r \Sigma_r G_{r,l}.$$  

Write $H = \Sigma_r G_{r,l}$ and let $H = S_H \Sigma_H T_H^T$ be compact SVD where $S_H$ is an $r \times r$ unitary matrix.

It follows that $S = S_r S_H$ is an $m \times r$ unitary matrix.

Hence $M_r B = S \Sigma_H T_H^T$ and $(M_r B)^+ = T_H (\Sigma_H)^+ S^T$ are compact SVDs of the matrices $M_r B$ and $(M_r B)^+$, respectively. Therefore $||(M_r B)^+|| = ||(\Sigma_H)^+|| = ||(\Sigma_r F_{r,l})^+|| \leq ||G_{r,l}^+|| \cdot ||\Sigma_r^{-1}||$. 

Substitute \( \|G_{r,l}^+\| = \nu_{r,l}^+ \) and \( \|\Sigma_r^{-1}\| = 1/\sigma_r(M) \) and obtain the theorem. 

\[ \square \]

Combine bounds (2.4.5), (2.4.6), and equation \( \|B\|_F = \nu_{F,n,l} \) and obtain claim (i) of Theorem 4.4.1. Combine that claim with claims (ii) of Theorem A.2.1 and (iii) of Theorem A.2.2 and obtain claim (ii) of Theorem 4.4.1.

2.4.5 Dual theorem: completion of the proof

**Theorem 2.4.6.** Suppose that \( U \in \mathbb{R}^{m \times r}, V \in \mathcal{G}^{r \times n}, \text{rank}(U) = r \leq \min\{m, n\}, M = UV, \) and \( B \) is a well-conditioned \( n \times l \) matrix of full rank \( l \) such that \( m \geq n > l \geq r \) and \( \|B\|_F = 1. \) Then

\[
\|(MB)^+\| \leq \|B^+\| \nu_{r,l}^+ \|U^+\|. 
\] (2.4.7)

If in addition \( U \in \mathcal{G}^{m \times r}, \) that is, if \( M \) is an \( m \times n \) factor-Gaussian matrix with expected rank \( r, \) then

\[
\|(MB)^+\| \leq \|B^+\| \nu_{m,r}^+ \nu_{r,l}^+. 
\]

**Proof.** Combine compact SVDs \( U = S_U \Sigma_U T_U^T, \) and \( B = S_B \Sigma_B T_B^T \) and obtain \( UVB = S_U \Sigma_U T_U^T V S_B \Sigma_B T_B^T. \) Here \( U, V, B, S_U, \Sigma_U, T_U, S_B, \Sigma_B, \) and \( T_B \) are matrices of the sizes \( m \times r, r \times n, n \times l, m \times r, r \times r, r \times r, n \times l, \) and \( l \times l, \) respectively.
Now observe that \( G_{r,l} = T_U^T V S_B \) is a \( r \times l \) Gaussian matrix, by virtue of Lemma A.2.1 (since \( V \) is a Gaussian matrix). Therefore \( U V B = S_U F T_B^T \), for \( F = \Sigma_U G_{r,l} \Sigma_B \).

Let \( F = S_F \Sigma_F T_F^T \) denote compact SVD where \( \Sigma_F = \text{diag}(\sigma_j(F))_{j=1}^r \) and \( S_F \) and \( T_F^T \) are unitary matrices of sizes \( r \times r \) and \( r \times l \), respectively.

Both products \( S_U S_F \in \mathbb{R}^{m \times r} \) and \( T_F^T T_B^T \in \mathbb{R}^{r \times l} \) are unitary matrices, and we obtain compact SVD \( M_B = U V B = S_{MB} \Sigma_{MB} T_{MB}^T \) where \( S_{MB} = S_U S_F \), \( \Sigma_{MB} = \Sigma_F \), and \( T_{MB} = T_F^T T_B^T \). Therefore

\[
\| (MB)^+ \| = \| \Sigma_{MB}^+ \| = \| \Sigma_F^+ \| = \| F^+ \|.
\]

\( \Sigma_B \) and \( \Sigma_V \) are square nonsingular diagonal matrices, and so

\[
F^+ = \Sigma_B^{-1} G_{r,l}^+ \Sigma_U^{-1}
\]

and

\[
\| (MB)^+ \| = \| F^+ \| \leq \| \Sigma_B^{-1} \| \| G_{r,l}^+ \| \| \Sigma_U^{-1} \| = \| B^+ \| \| \nu_{r,l}^+ \| \| U^+ \|.
\]

Combine (2.4.5), (2.4.7) and \( \| B \|_F \leq \| B \| \sqrt{l} \) and obtain Theorem 2.4.4 provided that \( M \) is a factor-Gaussian matrix \( UV \) with expected rank \( r \). By applying [S98, Corollary 1.4.19] for \( P = -C^{-1} E \) extend the results to the case where \( M = UV + E \) and the norm \( \| E \| \) is small, completing the proof of Theorem 2.4.4.
Remark 2.4.6. If \( U \in \mathcal{G}^{m \times r} \), for \( m - r \geq 4 \), then it is likely that \( \text{nrank}(U) = r \) by virtue of Theorem A.2.2, and our proof of bound (2.4.7) applies even if we assume that \( \text{nrank}(U) = r \) rather than \( U \in \mathcal{G}^{m \times r} \).

2.5 Generation of multipliers. Counting flops and random variables

In our tests we have consistently succeeded by using multipliers from a limited family of very sparse and highly structured orthogonal matrices (cf. classes 13–17 of Section 2.7.3), but in this section we also cover a greater variety of other sparse and structured matrices, which form an extended family of multipliers.

We proceed in the following order. Given two integers \( l \) and \( n \), \( l \ll n \), we first generate four classes of very sparse primitive \( n \times n \) unitary matrices, then combine them into some basic families of \( n \times n \) matrices (we denote them \( \hat{B} \) in this section), and finally define multipliers \( B \) as \( n \times l \) submatrices made up of \( l \) columns, which can be fixed (e.g., leftmost) or chosen at random. The matrix \( B \) is unitary if so is the matrix \( \hat{B} \), and more generally \( \kappa(B) \leq \kappa(\hat{B}) \) (cf. [GL13, Theorem 8.6.3]).
2.5.1 \( n \times n \) matrices of four primitive types

1. A fixed or random permutation matrix \( P \). Their block submatrices form the class of CountSketch matrices from the data stream literature (cf. [W14, Section 2.1], [CCF04], [TZ12]).

2. A diagonal matrix \( D = \text{diag}(d_i)_{i=0}^{n-1} \), with fixed or random diagonal entries \( d_i \) such that \( |d_i| = 1 \) for all \( i \) (and so all \( n \) entries \( d_i \) lie on the unit circle \( \{x : |z| = 1\} \), being either nonreal or \( \pm 1 \)).

3. An \( f \)-circular shift matrix \( Z_f = \begin{pmatrix} 0^T & f \\ I & 0 \end{pmatrix} \) and its transpose \( Z_f^T \) for a scalar \( f \) such that either \( f = 0 \) or \( |f| = 1 \). We write \( Z = Z_0 \), call \( Z \) unit down-shift matrix, and call the special permutation matrix \( Z_1 \) the unit circulant matrix.

4. A \( 2s \times 2s \) Hadamard primitive matrix \( H^{(2s)} = \begin{pmatrix} I_s & I_s \\ I_s & -I_s \end{pmatrix} \) for a positive integer \( s \) (cf. [M11], [W14]).

All our primitive \( n \times n \) matrices are very sparse and can be pre-multiplied by a vector in at most \( 2n \) flops. Except for the matrix \( Z \), they are unitary or real orthogonal, and so is any \( n \times l \) submatrix of \( Z \) of full rank \( l \). Next we combine primitives 1–4 into families of \( n \times n \) sparse and/or structured multipliers \( B \).
2.5.2 Family (i): multipliers based on the Hadamard and Fourier processes

At first we recall the following recursive definition of dense and orthogonal (up to scaling by constants) $n \times n$ matrices $H_n$ of Walsh-Hadamard transform for $n = 2^k$ (cf. [M11, Section 3.1] and our Remark 2.5.1):

$$H_{2q} = \begin{pmatrix} H_q & H_q \\ H_q & -H_q \end{pmatrix}$$

for $q = 2^h$, $h = 0, 1, \ldots, k - 1$, and the Hadamard primitive matrix $H_2 = H^{(2)} = \begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix}$ of type 4 for $s = 1$. E.g., $H_4 = \begin{pmatrix} 1 & 1 & 1 & 1 \\ 1 & -1 & 1 & -1 \\ 1 & 1 & -1 & -1 \\ 1 & -1 & -1 & 1 \end{pmatrix}$, but for larger dimensions $n$, recursive representation (2.5.1) enables much faster pre-multiplication of a matrix $H_n$ by a vector, namely it is sufficient to use $nk$ additions and subtractions for $n = 2^k$.

Next we sparsify this matrix by defining it by a shorter recursive process, that is, by fixing a recursion depth $d$, $1 \leq d < k$, and applying equation (2.5.1) where $q = 2^h s$, $h = k - d, k - d + 1, \ldots, k - 1$, and $H_s I_s$ for $n = 2^d s$.

For two positive integers $d$ and $s$, we denote the resulting $n \times n$ matrix $H_{n,d}$ and for $1 \leq d < k$ call it $d$–Abridged Hadamard (AH) matrix. In particular,

$$H_{n,1} = \begin{pmatrix} I_s & I_s \\ I_s & -I_s \end{pmatrix}, \text{ for } n = 2s; \quad H_{n,2} = \begin{pmatrix} I_s & I_s & I_s & I_s \\ I_s & -I_s & I_s & -I_s \\ I_s & I_s & -I_s & -I_s \\ I_s & -I_s & -I_s & I_s \end{pmatrix}, \text{ for } n = 4s,$$
CHAPTER 2. LOW-RANK APPROXIMATION: NEW INSIGHTS

For a fixed $d$, the matrix $H_{n,d}$ is still orthogonal up to scaling, has $q = 2^d$ nonzero entries in every row and column, and hence is sparse unless $k - d$ is a small integer. Then again, for larger dimensions $n$, we can pre-multiply such a matrix by a vector much faster if we represent it via recursive process (2.5.1), by using just $dn$ additions/subtractions and allows efficient parallel implementation (cf. Remark 2.5.4).

We similarly obtain sparse matrices by shortening a recursive process of the generation of the $n \times n$ matrix $\Omega_n$ of discrete Fourier transform (DFT) at $n$ points, for $n = 2^k$:

$$\Omega_n = (\omega_n^{ij})_{i,j=0}^{n-1}, \text{ for } n = 2^k \text{ and a primitive } n\text{th root of unity}$$

$$\omega_n = \exp\left(\frac{2\pi}{n}\sqrt{-1}\right). \text{ [E.g., } \Omega_2 = H^{(2)}].$$

The matrix $\Omega_n$ is unitary up to scaling by $\frac{1}{\sqrt{n}}$. We can pre-multiply it by a vector by using $1.5nk$ flops, and we can efficiently parallelize this computation if, instead of representation by entries, we apply following recursive
representation (cf. [P01, Section 2.3] and our Remark 2.5.1):\(^2\)

\[
\Omega_{2q} = \hat{P}_{2q} \begin{pmatrix} \Omega_q & \Omega_q D_q \\ \Omega_q D_q & -\Omega_q \end{pmatrix}, \quad \hat{D}_q = \text{diag}(\omega_i^{n-1})_{i=0}^{n-1}.
\] (2.5.3)

Here \(\hat{P}_{2q}\) is the matrix of odd/even permutations such that \(\hat{P}_{2q}^h(u) = v,\)

\[
u = (u_i)_{i=0}^{2^h-1}, \quad \nu_j = u_{2j}, \quad \nu_{j+2^h-1} = u_{2j+1}, \quad j = 0,1,\ldots,2^{h-1}-1;
\]

\(q = 2^h, \quad h = 0,1,\ldots,k,\) and \(\Omega_1 = (1)\) is the scalar 1.

We can sparsify this matrix by defining it by a shorter recursive process, that is, by fixing a recursion depth \(d, 1 \leq d < k,\) replacing \(\Omega_s\) for \(s = n/2^d\) by the identity matrix \(I_s,\) and then applying equation (4.3.3) for \(q = 2^h,\)

\(h = k - d, k - d + 1,\ldots,k - 1.\) For \(1 \leq d < k\) and \(n = 2^d s,\) we denote the resulting \(n \times n\) matrix \(\Omega_{n,d}\) and call it \(d\)-Abridged Fourier (AF) matrix. It is also unitary (up to scaling), has \(q = 2^d\) nonzero entries in every row and column, and thus is sparse unless \(k - d\) is a small integer. We can represent such a matrix by its entries, but then again its pre-multiplication by a vector involves just \(1.5dn\) flops and allows highly efficient parallel implementation if we rely on recursive representation (4.3.3).

By applying fixed or random permutation and scaling to \(AH\) matrices \(H_{n,d}\) and \(AF\) matrices \(\Omega_{n,d},\) we obtain the families of \(d\)-Abridged Scaled and

\(^2\)This is a representation of FFT, called decimation in frequency (DIF) radix-2 representation. Transposition turns it into an alternative representation of FFT, called decimation in time (DIT) radix-2 representation.
Permuted Hadamard (ASPH) matrices, PDH, and d–Abridged Scaled and Permutated Fourier (ASPF) $n \times n$ matrices, PD$\Omega$ where $P$ and $D$ are two matrices of permutation and diagonal scaling of primitive classes 1 and 2, respectively. Likewise we define the families of ASH, ASF, APH, and APF matrices, $DH_{n,d}$, $D\Omega_{n,d}$, $PH_{n,d}$, and $P\Omega_{n,d}$, respectively. Each random permutation or scaling contributes up to $n$ random parameters.

**Remark 2.5.1.** The following equations are equivalent to (2.5.1) and (4.3.3):

$$H_{2q} = \text{diag}(H_q, H_q) H^{(2q)} \quad \text{and} \quad \Omega_{2q} = \tilde{P}_{2q} \text{diag}(\Omega_q, \Omega_q \tilde{D}_q) H^{(2q)}.$$  

Here $H^{(2q)}$ denotes a $2q \times 2q$ Hadamard’s primitive matrix of type 4. By extending the latter recursive representation we can define matrices that involve more random parameters. Namely we can recursively incorporate random permutations and diagonal scaling as follows:

$$\tilde{H}_{2q} = P_{2q} D_{2q} \text{diag}(\tilde{H}_q, \tilde{H}_q) H^{(2q)} \quad \text{and} \quad \tilde{\Omega}_{2q} = P_{2q} D_{2q} \text{diag}(\Omega_q, \Omega_q \tilde{D}_q) H^{(2q)}.$$  

(2.5.4)

Here $P_{2q}$ are $2q \times 2q$ random permutation matrices of primitive class 1 and $D_{2q}$ are $2q \times 2q$ random matrices of diagonal scaling of primitive class 2, for all $q$. Then again we define d–abridged matrices $\tilde{H}_{n,d}$ and $\tilde{\Omega}_{n,d}$ by applying only $d$ recursive steps (2.5.4) initiated at the primitive matrix $I_s$, for $s = n/2^d$. 
With these recursive steps we can pre-multiply matrices $\hat{H}_{n,d}$ and $\hat{\Omega}_{n,d}$ by a vector by using at most $2dn$ additions and subtractions and at most $2.5dn$ flops, respectively, provided that $2^d$ divides $n$.

2.5.3 $f$-circulant, sparse $f$-circulant, and uniformly sparse matrices

An $f$-circulant matrix $Z_f(v) = \sum_{i=0}^{n-1} v_i Z_i^f$ for the matrix $Z_f$ of $f$-circular shift, is defined by a scalar $f \neq 0$ and by the first column $v = (v_i)_{i=0}^{n-1}$ and is called circulant if $f = 1$ and skew-circulant if $f = -1$. Such a matrix is nonsingular with probability 1 (see Theorem A.1.1) and is likely to be well-conditioned [PSZ15] if $|f| = 1$ and if the vector $v$ is Gaussian.

**Remark 2.5.2.** One can compute the product of an $n \times n$ circulant matrix with an $n \times n$ Toeplitz or Toeplitz-like matrix by using $O(n \log(n))$ flops (see [P01, Theorem 2.6.4 and Example 4.4.1]).

**FAMILY (ii)** of sparse $f$-circulant matrices $\hat{B} = Z_f(v)$ is defined by a fixed or random scalar $f$, $|f| = 1$, and by the first column having exactly $q$ nonzero entries, for $q \ll n$. The positions and the values of nonzeros can be randomized (and then the matrix would depend on up to $2n + 1$ random values).

Such a matrix can be pre-multiplied by a vector by using at most $(2q-1)n$
flops or, in the real case where $f = \pm 1$ and $v_i = \pm 1$ for all $i$, by using at most $qn$ additions and subtractions.

The same cost estimates apply in the case of the generalization of $Z_f(v)$ to a uniformly sparse matrix with exactly $q$ nonzeros entries, $\pm 1$, in every row and in every column for $1 \leq q \ll n$. Such a matrix is the sum $\hat{B} = \sum_{i=1}^{q} \hat{D}_i P_i$ for fixed or random matrices $P_i$ and $\hat{D}_i$ of primitive types 1 and 2, respectively.

### 2.5.4 Abridged $f$-circulant matrices

First recall the well-known expression $Z_g(v) = \sum_{i=0}^{n-1} v_i Z^i_g = D_f^{-1}\Omega_n^H D\Omega_n D_f$ where $g = f^n$, $D_f = \text{diag}(f^i)_{i=0}^{n-1}$, $\mathbf{v} = (v_i)_{i=0}^{n-1} = (\Omega_n D_f)^{-1}\mathbf{u}$, $\mathbf{u} = (u_i)_{i=0}^{n-1}$, and $D = \text{diag}(u_i)_{i=0}^{n-1}$ (cf. [P01, Theorem 2.6.4]). For $f = 1$, the expression is simplified: $g = 1$, $D_f = I_n$, and $Z_g(v)$ is a circulant matrix:

$$Z_1(v) = \Omega_n^H D\Omega_n, \quad D = \text{diag}(u_i)_{i=0}^{n-1}, \quad \text{for} \quad \mathbf{u} = (u_i)_{i=0}^{n-1} = \Omega_n \mathbf{v}. \quad (2.5.5)$$

Pre-multiplication of an $f$-circulant matrix by a vector is reduced to pre-multiplication of each of the matrices $\Omega$ and $\Omega^H$ by a vector and in addition to performing $4n$ flops (or $2n$ flops in case of a circulant matrix). This involves $O(n \log(n))$ flops overall and then again allows highly efficient parallel implementation.

For a fixed scalar $f$ and $g = f^n$, we can define the matrix $Z_g(v)$ by any
of the two vectors \( u \) or \( v \). The matrix is unitary (up to scaling) if \( |f| = 1 \) and if \( |u_i| = 1 \) for all \( i \) and is defined by \( n + 1 \) real parameters (or by \( n \) such parameters for a fixed \( f \)), which we can fix or choose at random.

Now suppose that \( n = 2^d s \), \( 1 \leq d < k \), \( d \) and \( k \) are integers, and substitute a pair of AF matrices of recursion length \( d \) for two factors \( \Omega_n \) in the above expressions. Then the resulting \textit{abridged \( f \)-circulant matrix} \( Z_{g,d}(v) \) of recursion depth \( d \) is still unitary (up to scaling), defined by \( n + 1 \) or \( n \) parameters \( u_i \) and \( f \), is sparse unless the positive integer \( k - d \) is small, and can be pre-multiplied by a vector by using \((3d + 3)n\) flops. Instead of AF matrices, we can substitute a pair of ASPF, APF, ASF, AH, ASPH, APH, or ASF matrices for the factors \( \Omega_n \). All such matrices form \textbf{FAMILY (iii)} of \( d \)-abridged \( f \)-circulant matrices.

**Remark 2.5.3.** Recall that an \( n \times l \) SRFT and SRHT matrices are the products \( \sqrt{n/l} \, D \Omega_n R \) and \( \sqrt{n/l} \, DH_n R \), respectively, where \( H_n \) and \( \Omega_n \) are the matrices of (2.5.1) and (2.5.2), \( D = \text{diag}(|u_i|)_{i=0}^{n-1} \), \( u_i \) are i.i.d. variables uniformly distributed on the circle \( \{ u : |u| = \sqrt{n/l} \} \), and \( R \) is the \( n \times l \) submatrix formed by \( l \) columns of the identity matrix \( I_n \) chosen uniformly at random. Equation (2.5.5) shows that we can obtain a SRFT matrix by pre-multiplying a circulant matrix by the matrix \( \Omega_n \) and post-multiplying it by the above matrix \( R \).
2.5.5 Inverses of bidiagonal matrices

**FAMILY (iv)** is formed by the inverses of $n \times n$ bidiagonal matrices $\hat{B} = (I_n + DZ)^{-1}$ or $\hat{B} = (I_n + Z^T D)^{-1}$ for a matrix $D$ of primitive type 2 and the down-shift matrix $Z$.

We pre-multiply a matrix $\hat{B} = (I_n + DZ)^{-1}$ by a vector $v$ by solving the linear system $(I_n + DZ)x = v$ in $2n - 1$ flops. In the real case we use just $n - 1$ additions and subtractions. We randomize this matrix $\hat{B}$ by choosing up to $n - 1$ random diagonal entries of the matrix $D$ (its leading entry makes no impact on $\hat{B}$).

Finally, $||\hat{B}|| \leq \sqrt{n}$ because nonzero entries of the lower triangular matrix $\hat{B} = (I_n + DZ)^{-1}$ have absolute values 1, and clearly $||\hat{B}^{-1}|| = ||I_n + DZ|| \leq \sqrt{2}$. Hence $\kappa(\hat{B}) = ||\hat{B}|| ||\hat{B}^{-1}||$ (the spectral condition number of $\hat{B}$) cannot exceed $\sqrt{2n}$ for $\hat{B} = (I_n + DZ)^{-1}$, and the same bound holds for $\hat{B} = (I_n + Z^T D)^{-1}$.

2.5.6 Summary of estimated numbers of flops and random variables involved

Table 2.5.1 shows upper bounds on

(a) the numbers of random variables involved into the $n \times n$ matrices $\hat{B}$ of the four families (i)–(iv) and
(b) the numbers of flops for pre-multiplication of such a matrix by a vector.\footnote{\textsuperscript{3}}

For comparison, using a Gaussian $n \times n$ multiplier involves $n^2$ random variables and $(2n - 1)n$ flops.

One can readily extend the estimates to $n \times l$ submatrices $B$ of the matrices $\hat{B}$.

\begin{table}
\centering
\begin{tabular}{|c|c|c|c|c|}
\hline
family & (i) AH & (i) ASPH & (ii) & (iii) \\
\hline
random variables & 0 & $2n$ & $2q + 1$ & $n$ \\
\hline
flops complex & $dn$ & $(d + 1)n$ & $(2q - 1)n$ & $(3d + 2)n$ \\
\hline
flops in real case & $dn$ & $(d + 1)n$ & $qn$ & $n - 1$ \\
\hline
\end{tabular}
\end{table}

\textbf{Remark 2.5.4.} Other observations besides flop estimates can be decisive. E.g., a special recursive structure of an ARSPH matrix $H_{2k,d}$ and an ARSPF matrix $\Omega_{2k,d}$ allows highly efficient parallel implementation of their pre-multiplication by a vector based on Application Specific Integrated Circuits (ASICs) and Field-Programmable Gate Arrays (FPGAs), incorporating Butterfly Circuits [DE].

\footnote{The asterisks in the table show that the matrices of families (i) AF, (i) ASPF, and (iii) involve nonreal roots of unity.}
2.5.7 Other basic families

There is a number of other interesting basic matrix families. According to [HMT11, Remark 4.6], “among the structured random matrices ..., one of the strongest candidates involves sequences of random Givens rotations”.

They are dense unitary matrices $\frac{1}{\sqrt{n}} D_1 G_1 D_2 G_2 D_3 \Omega_n$, for the DFT matrix $\Omega_n$, three random diagonal matrices $D_1$, $D_2$ and $D_3$ of primitive type 2, and two chains of Givens rotations $G_1$ and $G_2$, each of the form $G(\theta_1, \ldots, \theta_{n-1}) = P \prod_{i=1}^{n-1} G(i, i+1, \theta_i)$ for a random permutation matrix $P$,

$$G(i, i+1, \theta_i) = \text{diag}(I_{i-1}, \left( \frac{c_i s_i}{-s_i c_i}, I_{n-i-1} \right), c_i = \cos \theta_i, s_i = \sin \theta_i, c_i^2 + s_i^2 = 1).$$

Here $\theta_1, \ldots, \theta_{n-1}$ denote $n-1$ random angles of rotation uniformly distributed in the range $0 \leq \phi < 2\pi$.

The DFT factor $\Omega_n$ makes the resulting matrices dense, but we can sparsify them by replacing that factor by an AF, ASF, APF, or ASPF matrix having recursion depth $d < \log_2(n)$. This would also decrease the number of flops involved in pre-multiplication of such a multiplier by a vector from order $n \log_2(n)$ to $1.5dn + O(n)$. We can turn Givens sequences into distinct candidate families of efficient multipliers by replacing either or both of the Givens products with sparse matrices of Householder reflections matrices of the form $I_n - \frac{2hh^T}{h^T h}$ for fixed or random sparse vectors $h$ (cf. [GL13, Section 5.3.3]).
We can obtain a variety of multiplier families by combining matrices of basic families (i)–(iv) and the above matrices. Besides linear combinations, we can apply block representation as in the following real $2 \times 2$ block matrix
\[
\frac{1}{\sqrt{n}} \begin{pmatrix} Z_1(u) & Z_1(v) \\ Z_1(v) & -Z_1(u) \end{pmatrix} D
\]
d for two vectors $u$ and $v$ and a matrix $D$ of primitive class 2.

The reader can find other useful families of multipliers in our Section 2.7. E.g., according to our tests in Section 2.7, it turned out to be efficient to use nonsingular well-conditioned (rather than unitary) diagonal factors in the definition of some of our basic matrix families.

### 2.6 Managing the unlikely failure of Algorithm 2.3.1

#### 2.6.1 Some basic observations

**Theorem 2.6.1.** Given an $m \times n$ matrix $M$ with $\text{nrank}(M) = r$ and a reasonably small positive tolerance $\tau$, Algorithm 2.3.1 outputs SUCCESS if and only if $\text{nrank}(MB) = r$.

**Proof.** If $\text{rank}(MB) = r_- < r$, then $\text{rank}(\tilde{M}) \leq r_- < r$, $\Delta \geq \sigma_{r_-}(M)$. In this case $\Delta$ is not small because $\text{nrank}(M) = r > r_-$, and so Algorithm 2.3.1 applied to $M$ with the multiplier $B$ outputs FAILURE.
If \( \text{rank}(MB) = r > \text{nrank}(MB) = r_ - \) then \( \text{rank}(MB - E) = r_- < r \) for a small-norm perturbation matrix \( E \). Hence \( \Delta \geq \sigma_r(M) - O(||E||) \), and then again Algorithm 2.3.1 applied to \( M \) with the multiplier \( B \) outputs FAILURE. This proves the “only if” claim of the claim of Theorem 2.6.1.

Now let \( \text{nrank}(MB) = r \) and assume that we scale the matrix \( B \) so that \( ||B||_F = 1 \). Then \( \text{rank}(MB) = r \) (and so we can apply bound (2.4.5)), and furthermore \( \text{nrank}(Mr,B) = \text{nrank}(MB) = r \). Equation (2.4.5) implies that \( \Delta \approx 8\sqrt{8(n-r)}\sigma_{r+1}||(Mr,B)^+|| \). Therefore \( \Delta \) is a small positive value because \( \text{nrank}(M) = r \). Thus the value \( |\sigma_{r+1}| \) is small, and claim “if” of Theorem 2.6.1 follows.

**Definition 2.6.1.** For two integers \( l \) and \( n \), \( 0 < l \leq n \), and any fixed \( n \times l \) multiplier \( B \), partition the set of \( m \times n \) matrices \( M \) with \( \text{nrank}(M) = r \) into the set \( \mathcal{M}_B = \mathcal{M}_{B,\text{good}} \) of “\( B \)-good” matrices such that \( \text{nrank}(MB) = r \) and the set \( \mathcal{M}_{B,\text{bad}} \) of “\( B \)-bad” matrices such that \( \text{nrank}(MB) < r \).

The following simple observations should be instructive.

**Theorem 2.6.2.** (Cf. Remark 2.6.2.) Consider a vector \( v \) of dimension \( n \), an \( n \times n \) unitary matrix \( U \), and an \( n \times l \) unitary matrix \( B \), so that \( n \times l \) matrix \( UB \) is unitary. Then

(i) \( \mathcal{M}_{UB} = (\mathcal{M}_B)U \), that is, the map \( B \to UB \) multiplies the class \( \mathcal{M}_B \)
of $B$-good $m \times n$ matrices by the unitary matrix $U$,

(ii) $\mathcal{M}_B \subseteq \mathcal{M}(B \mid v)$, that is, appending a column to a multiplier $B$ can only expand the class $\mathcal{M}_B$, and

(iii) this class fills the whole space $C_{m,n,r}$ or $\mathbb{R}_{m,n,r}$ if $l = n$.

Proof. The relationships $(MU)B = M(UB)$ and

$$\text{nrank}(MB) \leq \text{nrank}(M(B \mid v))$$

imply claims (i) and (ii), respectively. Claim (iii) follows because

$$\text{nrank}(MB) = \text{nrank}(M)$$

if $B$ is an $n \times n$ unitary matrix. \hfill \Box

Remark 2.6.1. In view of claim (i) of Theorem 2.6.2, the results for the classes of SRFT and SRHT matrices also hold for the products of these classes with any unitary matrix, in particular for the class of $n \times l$ submatrices of an $n \times n$ circulant matrix, each made up of $l$ randomly chosen columns (see Remark 2.5.3).

2.6.2 A recursive algorithm

Based on Theorem 2.6.2 we devise the following algorithm where $\text{nrank}(M)$ is not known.
Algorithm 2.6.1. Recursive low-rank approximation. See Figure 1 and cf. [HMT11, Algorithm 4.2].

**Input:** An $m \times n$ matrix $M$ and a nonnegative tolerance $\tau$.

**Computation:** 1. Generate an $n \times n$ unitary matrix $\hat{B}$.

2. Fix positive integers $l_1, \ldots, l_h$ such that $l_1 + \cdots + l_h = n$ (in particular $l_j = 1$ for all $j$ if $h = n$) and represent the matrix $\hat{B}$ as a block vector $(B_1 \mid B_2 \mid \ldots \mid B_h)$ where the block $B_i$ has size $n \times l_i$ for $i = 1, \ldots, h$.

3. Recursively, for $i = 1, 2, \ldots$, apply Algorithm 2.3.1 to the matrix $M$ by substituting $l^{(i)} = \sum_{j=1}^{i} l_j$ for $l$ and $B^{(i)} = (B_1 \mid \ldots \mid B_i)$ for $B$. Stop If the algorithm outputs SUCCESS, output a rank-$r$ approximation of $M$ by applying [HMT11, Algorithm 5.2].

Figure 2.1: Matrices of Algorithm 2.6.1

Remark 2.6.2. One can readily extend the algorithm by using a nonsingular and well-conditioned (rather than unitary) $n \times n$ matrix $\hat{B}$. Then all multipliers $B^{(i)}$ and their blocks $B_j$ are also well-conditioned matrices of full rank; moreover $\kappa(B^{(i)}) \leq \kappa(B)$ and $\kappa(B_j) \leq \kappa(B)$ for all $i$ and $j$ (cf. [GL13, Corollary 8.6.3]).
The complexity of the algorithm is dominated at Stage 1, which uses from \((2n - 1)ml\) flops for generic matrices \(M\) and \(B\) to order of \(mn\) for sparse and structured multipliers \(B\) even where \(l = n\).

**Our conflicting goals and simple recipes.** We try to decrease:

(i) the cost of the generation of a multiplier \(B\) and of the computation of the matrix \(MB\),

(ii) the chances for the failure of Algorithm 2.3.1, and

(iii) the rank of the computed approximation of a matrix \(M\).

Towards goal (i) we apply sparse and structured \(n \times l\) multipliers. Towards goal (ii) we can expect to succeed whenever integer parameter \(l\) exceeds \(r + 1\), but our chances for success grow fast as \(l\) increases. Such an increase is in conflict with our goal (iii), but we can alleviate the problem by using the following heuristic technique, which consistently worked in our extensive tests for benchmark inputs in Section 2.7.

**Heuristic Compression Algorithm** (linear combination of failed multipliers): if the first \(h\) recursive steps of Algorithm 2.6.1 have failed for \(h > 1\), then apply Algorithm 2.3.1 with a multiplier \(B = \sum_{j=1}^{h} c_j B_j\) where \(c_j = \pm 1\) for all \(j\) and for a fixed or random choice of the signs \(\pm\). (More generally, one can choose complex values \(c_j\) on the unit circle, letting \(|c_j| = 1\) for all \(j\).)
CHAPTER 2. LOW-RANK APPROXIMATION: NEW INSIGHTS

2.7 Numerical Tests

Numerical experiments have been performed by Xiaodong Yan for Tables 4.6.1–4.6.3 and by John Svadlenka and Liang Zhao for the other tables. The report [PSZa] displays graphs of the same data. The tests have been run by using MATLAB in the Graduate Center of the City University of New York on a Dell computer with the Intel Core 2 2.50 GHz processor and 4G memory running Windows 7; in particular the standard normal distribution function randn of MATLAB has been applied in order to generate Gaussian matrices.

We calculated the $\xi$-rank, i.e., the number of singular values exceeding $\xi$, by applying the MATLAB function "svd()". We have set $\xi = 10^{-5}$ in Sections 2.7.1 and 2.7.2 and $\xi = 10^{-6}$ in Section 2.7.3.

2.7.1 Tests for inputs generated via SVD

In the tests of this subsection we generated $n \times n$ input matrices $M$ by extending the customary recipes of [H02, Section 28.3]. Namely, we first generated matrices $S_M$ and $T_M$ by means of the orthogonalization of $n \times n$ Gaussian matrices. Then we defined $n \times n$ matrices $M$ by their compact SVDs, $M = S_M \Sigma_M T_M^T$, for $\Sigma_M = \text{diag}(\sigma_j)_{j=1}^n$; $\sigma_j = 1/j$, $j = 1, \ldots, r$, $\sigma_j = 10^{-10}$, $j = r + 1, \ldots, n$, and $n = 256, 512, 1024$. (Hence $\|M\| = 1$ and
\( \kappa(M) = \|M\| \|M^{-1}\| = 10^{10}. \)

Table 2.7.1 shows the average output error norms \( \Delta \) over 1000 tests of Algorithm 2.3.1 applied to these matrices \( M \) for each pair of \( n \) and \( r \), \( n = 256, 512, 1024 \), \( r = 8, 32 \), and each of the following three groups of multipliers: 3-AH multipliers, 3-ASPH multipliers, both defined by Hadamard recursion (4.3.3), for \( d = 3 \), and dense multipliers \( B = B(\pm 1, 0) \) having i.i.d. entries \( \pm 1 \) and 0, each value chosen with probability 1/3.

</tr>
</tbody>
</table>

2.5.3 (for $q = 10$) having the first column vectors $v$ filled with zeros, except for ten random coordinates filled with random integers ±1.

**Basic Set 3:** Sum of two scaled inverse bidiagonal matrices. We first filled the main diagonals of both matrices with the integer 101 and their first subdiagonals with ±1. Then we multiplied each matrix by a diagonal matrix $\text{diag}(\pm 2^{b_i})$, where $b_i$ were random integers uniformly chosen from 0 to 3.

For multipliers $B$ we used the $n \times r$ western (leftmost) blocks of $n \times n$ matrices of the following classes:

1. a matrix from Basic Set 1;
2. a matrix from Basic Set 2;
3. a matrix from Basic Set 3;
4. the product of two matrices of Basic Set 1;
5. the product of two matrices of Basic Set 2;

6. the product of two matrices of Basic Set 3;

7. the sum of two matrices of Basic Sets 1 and 3, and

8. the sum of two matrices of Basic Sets 2 and 3.

The tests produced the results similar to the ones of Tables 2.7.1–4.6.3.

In sum, for all classes of input pairs $M$ and $B$ and all pairs of integers $n$ and $r$, Algorithm 2.3.1 with our pre-processing has consistently output approximations to rank-$r$ input matrices with the average error norms ranged from $10^{-7}$ or $10^{-8}$ to about $10^{-9}$ in all our tests.

2.7.2 Tests for inputs generated via the discretization of a Laplacian operator and via the approximation of an inverse finite-difference operator

Next we present the test results for Algorithm 2.3.1 applied to input matrices for computational problems of two kinds, both replicated from [HMT11], namely, the matrices of

(i) the discretized single-layer Laplacian operator and

(ii) the approximation of the inverse of a finite-difference operator.

Input matrices (i). We considered the Laplacian operator \( [S\sigma](x) = c \int_{\Gamma_1} \log |x - y\sigma(y)|dy, x \in \Gamma_2, \) from [HMT11, Section 7.1], for two contours \( \Gamma_1 = C(0, 1) \) and \( \Gamma_2 = C(0, 2) \) on the complex plane. Its discretization defines an \( n \times n \) matrix \( M = (m_{ij})_{i,j=1}^n \) where \( m_{ij} = c \int_{\Gamma_{1,j}} \log |2\omega_i - y|dy \) for a constant \( c \) such that \( ||M|| = 1 \) and for the arc \( \Gamma_{1,j} \) of the contour \( \Gamma_1 \) defined by the angles in the range \( \left[ \frac{2j\pi}{n}, \frac{2(j+1)\pi}{n} \right] \).

We applied Algorithm 2.3.1 supported by three iterations of the Power Scheme of Remark 2.4.5 and used with multipliers \( B \) being the \( n \times r \) leftmost submatrices of \( n \times n \) matrices of the following five classes:

- Gaussian multipliers,

- Gaussian Toeplitz multipliers \( T = (t_{i-j})_{i=0}^{n-1} \) for i.i.d. Gaussian variables \( t_{1-n}, \ldots, t_{-1}, t_0, t_1, \ldots, t_{n-1} \).
• Gaussian circulant multipliers $\sum_{i=0}^{n-1} v_i Z_i^1$, for i.i.d. Gaussian variables $v_0, \ldots, v_{n-1}$ and the unit circular matrix $Z_1$ of Section 2.5.1.

• Abridged permuted Fourier (3-APF) multipliers, and

• Abridged permuted Hadamard (3-APH) multipliers.

As in the previous subsection, we defined each 3-APF and 3-APH matrix by applying three recursive steps of equation (4.3.3) followed by a single random column permutation.

We applied Algorithm 2.3.1 with multipliers of all five listed classes. For each setting we repeated the test 1000 times and calculated the mean and standard deviation of the error norm $||\tilde{M} - M||$.

Input matrices (ii). We similarly applied Algorithm 2.3.1 to the input matrix $M$ being the inverse of a large sparse matrix obtained from a finite-difference operator of [HMT11, Section 7.2] and observed similar results with all structured and Gaussian multipliers.

We performed 1000 tests for every class of pairs of $n \times n$ or $m \times n$ matrices of classes (i) or (ii), respectively, and $n \times r$ multipliers for every fixed triple of $m$, $n$, and $r$ or pair of $n$ and $r$.

Tables 2.7.6 and 2.7.7 display the resulting mean values and standard deviation of the error norms.

</table>

of multipliers (besides its control application with Gaussian multipliers). We tested Algorithm 2.3.1 applied to $1024 \times 1024$ SVD-generated input matrices having numerical nullity $r = 32$, to $400 \times 400$ Laplacian input matrices having numerical nullity $r = 3$, and to $408 \times 800$ matrices having numerical nullity $r = 64$ and representing finite-difference inputs.

Then again we repeated the tests 1000 times for each class of input matrices and each size of an input and a multiplier, and we display the resulting average error norms in Table 2.7.3.
We used multipliers defined as the seventeen sums of $n \times r$ matrices of the following basic families:

- 3-ASPH matrices
- 3-APH matrices
- Inverses of bidiagonal matrices
- Random permutation matrices

We defined every 3-APH matrix by three Hadamard’s recursive steps (2.5.1) followed by random permutation, and we similarly defined every 3-ASPH matrix, but also applied random scaling with a diagonal matrix $D = \text{diag}(d_i)_{i=1}^n$ choosing the values of random i.i.d. variables $d_i$ uniformly from the set $\{1/4, 1/2, 1, 2, 4\}$. We permuted all inverses of bidiagonal matrices except for Class 5 of multipliers.

Describing our multipliers we use the following acronyms and abbreviations: “IBD” for “the inverse of a bidiagonal”, “MD” for “the main diagonal”, “SB” for “subdiagonal”, and “SP” for “superdiagonal”. We write “MD$i$”, “$k$th SB$i$” and “$k$th SP$i$” in order to denote that the main diagonal, the $k$th subdiagonal, or the $k$th superdiagonal of a bidiagonal matrix, respectively, was filled with the integer $i$. 
• Class 0: Gaussian

• Class 1: Sum of a 3-ASPH and two IBD matrices:
  B1 with MD−1 and 2nd SB−1 and B2 with MD+1 and 1st SP+1

• Class 2: Sum of a 3-ASPH and two IBD matrices:
  B1 with MD+1 and 2nd SB−1 and B2 with MD+1 and 1st SP−1

• Class 3: Sum of a 3-ASPH and two IBD matrices:
  B1 with MD+1 and 1st SB−1 and B2 with MD+1 and 1st SP−1

• Class 4: Sum of a 3-ASPH and two IBD matrices:
  B1 with MD+1 and 1st SB+1 and B2 with MD+1 and 1st SP−1

• Class 5: Sum of a 3-ASPH and two IBD matrices:
  B1 with MD+1 and 1st SB+1 and B2 with MD+1 and 1st SP−1

• Class 6: Sum of a 3-ASPH and three IBD matrices:
  B1 with MD−1 and 2nd SB−1, B2 with MD+1 and 1st SP+1 and B3 with MD+1 and 9th SB+1

• Class 7: Sum of a 3-ASPH and three IBD matrices:
  B1 with MD+1 and 2nd SB−1, B2 with MD+1 and 1st SP−1, and B3 with MD+1 and 8th SP+1
• Class 8: Sum of a 3-ASPH and three IBD matrices:
  B1 with MD+1 and 1st SB−1, B2 with MD+1 and 1st SP−1, and B3 with MD+1 and 4th SB+1

• Class 9: Sum of a 3-ASPH and three IBD matrices:
  B1 with MD+1 and 1st SB+1, B2 with MD+1 and 1st SP−1, and B3 with MD−1 and 3rd SP+1

• Class 10: Sum of three IBD matrices:
  B1 with MD+1 and 1st SB+1, B2 with MD+1 and 1st SP−1, and B3 with MD−1 and 3rd SP+1

• Class 11: Sum of a 3-APH and three IBD matrices:
  B1 with MD+1 and 2nd SB−1, B2 with MD+1 and 1st SP−1, and B3 with MD+1 and 8th SP+1

• Class 12: Sum of a 3-APH and two IBD matrices:
  B1 with MD+1 and 1st SB−1 and B2 with MD+1 and 1st SP−1

• Class 13: Sum of a 3-ASPH and a permutation matrix

• Class 14: Sum of a 3-ASPH and two permutation matrices

Table 2.7.8: Relative Error Norm in Tests with Multipliers of Additional Classes

The outputs were quite accurate even where we used very sparse multipliers of classes 13–17.
2.8 A Brief Summary

In this chapter we

(i) supplied a missing formal support for well-known empirical observations,

(ii) defined new efficient policies of generation and application of multipliers for low-rank approximation,

(iii) successfully tested our policies numerically, and

(iv) extended our progress to other important areas of matrix computations.

Chapter 3

LDR Neural Network

3.0.1 LDR Neural Networks

In this chapter we study application of LDR matrices in neural networks. Without loss of generality, we focus on a feed-forward neural network with one fully-connected (hidden) layer, which is similar to the network setup in [4]. Here the input layer (with \( n \) neurons) and the hidden layer (with \( kn \) neurons)\(^1\) are assumed to be fully connected with a weight matrix \( W \in \mathbb{R}^{n \times kn} \) of displacement rank at most \( r \) corresponding to displacement operators \((A, B)\), where \( r \ll n \). The domain for the input vector \( x \) is the \( n \)-dimensional hypercube \( I^n := [0,1]^n \), and the output layer only contains one neuron. The neural network can be expressed as:

\[
y = G_{W, \theta}(x) = \sum_{j=1}^{kn} \alpha_j \sigma(w_j^T x + \theta_j).
\]  

\(^1\)Please note that this assumption does not sacrifice any generality because the \( n \)-by-\( m \) case can be transformed to \( n \)-by-\( kn \) format with the nearest \( k \) by using zero padding [3].
Here $\sigma(\cdot)$ is the activation function, $w_j \in \mathbb{R}^n$ denotes the $j$-th column of the weight matrix $W$, and $\alpha_j, \theta_j \in \mathbb{R}$ for $j = 1, \ldots, kn$. When the weight matrix $W = [w_1 | w_2 | \cdots | w_{kn}]$ has a low-rank displacement, we call it an LDR neural network. Matrix displacement techniques ensure that LDR neural network has much lower space requirement and higher computational speed comparing to classical neural networks of similar size.

3.0.2 Problem Statement

In this chapter, we aim at providing theoretical support on the accuracy of function approximation using LDR neural networks, which represents the “effectiveness” of LDR neural networks compared with the original neural networks. Given a continuous function $f(x)$ defined on $[0, 1]^n$, we study the following tasks:

- For any $\epsilon > 0$, find an LDR weight matrix $W$ such that the function defined by equation (4) satisfies
  \[ \max_{x \in [0,1]^n} |f(x) - G_{W,\theta}(x)| < \epsilon. \quad (3.0.2) \]

- Fix a positive integer $n$, find an upper bound $\epsilon$ so that for any continuous function $f(x)$ there exists a bias vector $\theta$ and an LDR matrix with at most $n$ rows satisfying equation (3.0.2).
• Find a multi-layer LDR neural network that achieves error bound (3.0.2) but with fewer parameters.

The first task is handled in Section 3.1, which is the universal approximation property of LDR neural networks. It states that the LDR neural networks could approximate any continuous function arbitrarily well, and this has widespread applications. The error bounds for shallow and deep neural networks are derived in Section 5. In addition, we derived explicit back-propagation expressions for LDR neural networks in Section 3.3.

3.1 The Universal Approximation Property of LDR Neural Networks

In this section we first prove a theorem for matrix displacements. Based on it, we prove the universal approximation property of neural networks utilizing only LDR matrices.

Theorem 3.1.1. Let $A$, $B$ be two $n \times n$ non-singular diagonalizable matrices satisfying:

i) $A^q = aI$ for some positive integer $q \leq n$ and a scalar $a \neq 0$; ii) $(I-aB^q)$ is nonsingular; iii) the eigenvalues of $B$ have distinct absolute values.

Define $S$ as the set of matrices $M$ such that $\Delta_{A,B}(M)$ has rank 1, i.e.,

$$S_{A,B} = \{ M \in \mathbb{R}^{n \times n} | \exists g, h \in \mathbb{R}^n, \Delta_{A,B}(M) = gh^T \}. \quad (3.1.1)$$
Then for any vector \( \mathbf{v} \in \mathbb{R}^n \), there exists a matrix \( \mathbf{M} \in S_{\mathbf{A}, \mathbf{B}} \) and an index \( v \in \{1, \ldots, n\} \) such that the \( i \)-th column of \( \mathbf{M} \) equals vector \( \mathbf{v} \).

**Proof.** By the property of Stein displacement, any matrix \( \mathbf{M} \in S \) can be expressed in terms of \( \mathbf{A}, \mathbf{B} \), and its displacement as follows:

\[
\mathbf{M} = \sum_{k=0}^{q-1} \mathbf{A}^k \Delta_{\mathbf{A}, \mathbf{B}}(\mathbf{M}) \mathbf{B}^k (\mathbf{I} - a\mathbf{B}^q)^{-1}.
\]

(3.1.2)

Here we use the property that \( \Delta_{\mathbf{A}, \mathbf{B}}(\mathbf{M}) \) has rank 1, and thus it can be written as \( \mathbf{g} \cdot \mathbf{h}^T \). Since \( \mathbf{A} \) is diagonalizable, one can write its eigen-decomposition as

\[
\mathbf{A} = \mathbf{Q}^{-1} \Lambda \mathbf{Q}.
\]

(3.1.3)

where \( \Lambda = \text{diag}(\lambda_1, ..., \lambda_n) \) is a diagonal matrix generated by the eigenvalues of \( \mathbf{A} \). Now define \( \mathbf{e}_j \) to be the \( j \)-th unit column vector for \( j = 1, ..., n \). Write

\[
\mathbf{Q}\mathbf{M}\mathbf{e}_j = Q \sum_{k=0}^{q-1} \mathbf{A}^k \Delta_{\mathbf{A}, \mathbf{B}}(\mathbf{M}) \mathbf{B}^k (\mathbf{I} - a\mathbf{B}^q)^{-1} \mathbf{e}_j \\
= Q \sum_{k=0}^{q-1} (\mathbf{Q}^{-1} \Lambda \mathbf{Q})^k \mathbf{g} \mathbf{h}^T \mathbf{B}^k (\mathbf{I} - a\mathbf{B}^q)^{-1} \mathbf{e}_j \\
= (\sum_{k=0}^{q-1} s_{h,j} \mathbf{A}^k) \mathbf{Q} \mathbf{g}.
\]

(3.1.4)

Here \( s_{h,j} \) denotes the scalar value \( \mathbf{h}^T \mathbf{B}^k (\mathbf{I} - a\mathbf{B}^q)^{-1} \mathbf{e}_j \) for \( k = 1, ..., n \). Define \( \mathbf{T} := (\mathbf{I} - a\mathbf{B}^q)^{-1} \). In order to prove the theorem, we need to show that there exists a vector \( \mathbf{h} \) and an index \( k \) such that the matrix \( \sum_{k=0}^{q-1} s_{h,j} \mathbf{A}^k \)
is nonsingular. In order to distinguish scalar multiplication from matrix multiplication, we write \( a \circ M \) to denote the product of a scalar \( a \) and a matrix \( M \). Rewrite the expression as

\[
\sum_{k=0}^{q-1} s_{h,j} A^k
\]

\[
= \sum_{k=0}^{q-1} h^T \cdot (B^k T e_j \circ \text{diag}(\lambda_1^k, \ldots, \lambda_n^k))
\]

\[
= \sum_{k=0}^{q-1} \text{diag}(h^T \cdot B^k \cdot (\lambda_1^k e_j | \cdots | \lambda_n^k e_j))
\]

\[
= \text{diag} \left( h^T \cdot \left( \sum_{k=0}^{q-1} B^k T \lambda_1^k e_j \right), \ldots, h^T \cdot \left( \sum_{k=0}^{q-1} B^k T \lambda_n^k e_j \right) \right).
\]

The diagonal matrix \( \sum_{k=0}^{q-1} s_{h,j} A^k \) is nonsingular if and only if all of its diagonal entries are nonzero. Let \( b_{ij} \) denote the column vector \( \sum_{k=0}^{q-1} BT^k \lambda_i^k e_j \). Unless for every \( j \) there is an index \( i_j \) such that \( b_{i_j,j} = 0 \), we can choose a vector \( h \) such that the resulting diagonal matrix is nonsingular. Next we prove by contradiction that the former case is not possible. Assume that there is a column \( b_{i,j} = 0 \) for every \( j = 1, 2, \ldots, n \), we must have:

\[
0 = [b_{i,1} | b_{i,2} | \cdots | b_{i,n}]
\]

\[
= \left[ \sum_{k=0}^{q-1} B^k T \lambda_1^k e_1 | \cdots | \sum_{k=0}^{q-1} B^k T \lambda_n^k e_n \right]
\]

\[
= \sum_{k=0}^{q-1} B^k T \cdot \text{diag}(\lambda_1^k, \ldots, \lambda_n^k).
\]
Since \( B \) is diagonalizable, we write \( B = P^{-1} \Pi P \), where \( \Pi = \text{diag}(\eta_1, \ldots, \eta_n) \).

Also we have \( T = (I - aB^q)^{-1} = P^{-1}(I - a\Pi^q)^{-1}P \). Then

\[
0 = \sum_{k=0}^{q-1} BT^k \text{diag}(\lambda_i^k_{1}, \ldots, \lambda_i^k_{n})
= P^{-1} \left[ \sum_{k=0}^{q-1} \Pi^k (I - a\Pi^q)^{-1} \text{diag}(\lambda_i^k_{1}, \ldots, \lambda_i^k_{n}) \right] P
= P^{-1} \sum_{k=0}^{q-1} \text{diag} \left( (\lambda_i \eta_1)^k, \ldots, (\lambda_i \eta_n)^k \right) (I - a\Pi^q)^{-1} P
= P^{-1} \text{diag} \left( \sum_{k=0}^{q-1} (\lambda_i \eta_1)^k, \ldots, \sum_{k=0}^{q-1} (\lambda_i \eta_n)^k \right) (I - a\Pi^q)^{-1} P.
\]

This implies that \( \lambda_i \eta_1, \ldots, \lambda_i \eta_n \) are solutions to the equation

\[
1 + x + x^2 + \cdots + x^{q-1} = 0. \quad (3.1.5)
\]

By assumption of matrix \( B \), \( \eta_1, \ldots, \eta_k \) have different absolute values, and so are \( \lambda_i \eta_1, \ldots, \lambda_i \eta_1 \), since all \( \lambda_k \) have the same absolute value because \( A^q = aI \).

It would follow that there are \( q \) distinct solutions of equation (3.1.5), but this is impossible, and so the matrix \( \sum_{k=0}^{q-1} s_{h,j} A^k \) cannot be singular for all \( h \in \mathbb{R}^n \). With this property proven, given any vector \( v \in \mathbb{R}^n \), one can take the following procedure to find a matrix \( M \in S \) and an index \( j \) such that the \( j \)-th column of \( M \) equals \( v \):

i) Find a vector \( h \) and a index \( j \) such that matrix \( \sum_{k=0}^{q-1} s_{h,j} A^k \) is non-singular;
ii) By equation \((3.1.4)\), find
\[
g := Q^{-1}\left( \sum_{k=0}^{q-1} s_{h,j} \Lambda^k \right)^{-1} QT v;
\]
iii) Construct \(M \in S\) with \(g\) and \(h\) defined by equation \((3.1.2)\). Then the \(j\)-th column of \(M\) is equal to \(v\).

With the above construction, we have shown that for any vector \(v \in \mathbb{R}^n\) one can find a matrix \(M \in S\) and an index \(j\) such that the \(j\)-th column of \(M\) equals \(v\); thus the theorem is proved.

Our main goal of this section is to show that neural networks with many types of LDR matrices (LDR neural networks) can approximate continuous functions arbitrarily well. In particular, we are going to show that Toeplitz and circulant matrices, being specific cases of LDR matrices, have this property. In order to do so, we need to introduce the following definition of a discriminatory function and a key property (cf. [4])

**Definition 3.1.1.** A function \(\sigma(u) : \mathbb{R} \to \mathbb{R}\) is called as discriminatory if the zero measure is the only measure \(\mu\) that satisfies the following property:

\[
\int_{\mathbb{R}^n} \sigma(w^T x + \theta) d\mu(x) = 0, \forall w \in \mathbb{R}^n, \theta \in \mathbb{R}.
\]

**Lemma 3.1.1.** Any bounded, measurable sigmoidal function is discriminatory.
CHAPTER 3. LDR NEURAL NETWORK

Proof. The statement of this lemma and its proof is included in [4]. \qed

Now we are ready to present the universal approximation theorem of LDR neural networks with \( n \)-by-\( kn \) weight matrix \( W \):

**Theorem 3.1.2** (Universal Approximation Theorem for LDR Neural Networks). Let \( \sigma \) be any continuous discriminatory function. For any continuous function \( f(x) \) defined on \( I^n \), \( \epsilon > 0 \), and any \( A, B \in \mathbb{R}^{n \times n} \), satisfying assumptions in Theorem 3.1.1, then there exists a function \( G(x) \) in the form of equation (3.0.1) so that its weight matrix consists of \( k \) submatrices with displacement rank of 1 and

\[
\max_{x \in I^n} |G(x) - f(x)| < \epsilon. \tag{3.1.7}\]

Proof. Denote the \( i \)-th \( n \times n \) submatrix of \( W \) as \( W_i \). Then \( W \) can be written as

\[
W = [W_1|W_2|...|W_k]. \tag{3.1.8}\]

Let \( M \) be any of submatirx \( W_i \) with displacement rank 1. \( M \) can be written as

\[
\Delta_{A,B}(M) = M - AMB = g \cdot h^T, \tag{3.1.9}\]

where \( g, h \in \mathbb{R}^n \).
Since \( A^q = I \), then obtain

\[
M = \left[ \sum_{k=0}^{q-1} A^k \Delta_{A,B}(M)B^k \right] (I - aB^q)^{-1}.
\]  

(3.1.10)

Let \( S_{I^n} \) denote the set of all continuous functions defined on \( I^n \). Let \( U_{I^n} \) be the linear subspace of \( S_{I^n} \) that can be expressed in form of equation (3.0.1) where \( W \) consists of \( k \) sub-matrices with displacement rank 1. We want to show that \( U_{I^n} \) is dense in the set of all continuous functions \( S_{I^n} \).

Suppose it is not dense. Then, by virtue of the Hahn-Banach Theorem, there exists a bounded linear functional \( L \neq 0 \) such that \( L(\bar{U}(I^n)) = 0 \). Moreover, by by virtue of the Riesz Representation Theorem, \( L \) can be written as

\[
L(h) = \int_{I^n} h(x)d\mu(x), \forall h \in S(I^n),
\]

for some measure \( \mu \).

Next we show that for any \( y \in \mathbb{R}^n \) and \( \theta \in \mathbb{R} \), the function \( \sigma(y^T x + \theta) \) belongs to the set \( U_{I^n} \), and thus we must have

\[
\int_{I^n} \sigma(y^T x + \theta)d\mu(x) = 0.
\]  

(3.1.11)

For any vector \( y \in \mathbb{R}^n \), Theorem 3.1.1 guarantees that there exists an \( n \times n \) LDR matrix \( M = [b_1|\cdots|b_n] \) and an index \( j \) such that \( b_j = y \). Now define
CHAPTER 3. LDR NEURAL NETWORK

a vector \((\alpha_1, \ldots, \alpha_n)\) such that \(\alpha_j = 1\) and \(\alpha_1 = \cdots = \alpha_n = 0\). Also let the value of all bias be \(\theta\). Then the LDR neural network function becomes

\[
G(x) = \sum_{i=1}^{n} \alpha_i \sigma(b_i^T x + \theta) = \alpha_j \sigma(b_j^T x + \theta) = \sigma(y^T x + \theta).
\]

From the fact that \(L(G(x)) = 0\), we derive that

\[
0 = L(G(x)) = \int_{I^n} \sum_{i=1}^{n} \alpha_i \sigma(b_i^T x + \theta) = \int_{I^n} \sigma(y^T x + \theta) d\mu(x).
\]

Since \(\sigma(t)\) is a discriminatory function by Lemma 3.1.1. We can conclude that \(\mu\) is the zero measure. As a result, the function defined as an integral with measure \(\mu\) must be zero for any input function \(h \in S(I^n)\). The last statement contradicts the property that \(L \neq 0\) from the Hahn-Banach Theorem, which is obtained based on the assumption that the set \(U_{I^n}\) of LDR neural network functions are not dense in \(S_{I^n}\). As this assumption is not true, we have the universal approximation property of LDR neural networks.

The papers [3], [15] have utilized a circulant matrix or a Toeplitz matrix for weight representation in deep neural networks. Please notice that in the general case of \(n\)-by-\(m\) weight matrices, either the more general Block-circulant matrices should be utilized or padding extra columns or rows of zeroes are needed [3]. Circulant matrices and Toeplitz matrices are both
special form of LDR matrices, and thus we could apply the above universal approximation property of LDR neural networks and provide theoretical support for the use of circulant and Toeplitz matrices in [3], [15]. Although circulant and Toeplitz matrices have displacement rank of 2 instead of 1, the property of Theorem 3.1.1 still holds, as a Toeplitz matrix is completely determined by its first row and its first column (and a circulant matrix is completely determined by its first row.) Therefore we arrive at the following corollary.

**Corollary 3.1.1.** *Any continuous function can be arbitrarily approximated by neural networks constructed with Toeplitz matrices or circulant matrices (with padding or using Block-circulant matrices).*

### 3.2 Error Bounds on LDR Neural Networks

Having the universal approximation property proved, we seek error estimates for LDR neural networks. We prove that for LDR matrices defined by $O(n)$ parameters ($n$ represents the number of rows and has the same order as the number of columns), the corresponding structured neural network is capable of achieving integrated squared error of order $O(1/n)$, where $n$ is the number of parameters. This result is asymptotically equivalent to Barron’s aforementioned result on general neural networks, indicating that there is essentially
no loss for restricting to LDR matrices.

The functions we would like to approximate are those who are defined on a $n$-dimensional ball $B_r = \{ x \in \mathbb{R}^n : |x| \leq r \}$ such that $\int_{B_r} |x||f(x)||\mu(dx) \leq C$, where $\mu$ is an arbitrary measure normalized so that $\mu(B_r) = 1$. Let us denote this set $\Gamma_{C,B_r}$.

[1] considered the following set of bounded multiples of a sigmoidal function composed with linear functions:

$$G_\sigma = \{ \alpha \sigma(y^T x + \theta) : |\alpha| \leq 2C, y \in \mathbb{R}^n, \theta \in \mathbb{R} \}. \quad (3.2.1)$$

He proved the following theorem:

**Theorem 3.2.1 ([1]).** For every function in $\Gamma_{C,B_r}$, every sigmoidal function $\sigma$, every probability measure, and every $k \geq 1$, there exists a linear combination of sigmoidal functions $f_k(x)$ of the form

$$f_k(x) = \sum_{j=1}^{k} \alpha_j \sigma(y_j^T x + \theta_j), \quad (3.2.2)$$

such that

$$\int_{B_r} (f(x) - f_k(x))^2 \mu(dx) \leq \frac{4r^2C}{k}. \quad (3.2.3)$$

Here $y_j \in \mathbb{R}^n$ and $\theta_j \in \mathbb{R}$ for every $j = 1, 2, ..., N$. Moreover, the coefficients of the linear combination may be restricted to satisfy $\sum_{j=1}^{k} |c_j| \leq 2rC$. 
Next we will obtain a similar result for LDR matrices. Fix operator 
\((A, B)\) and define

\[
S_{\sigma}^{kn} = \left\{ \sum_{j=1}^{kn} \alpha_j \sigma(y_j^T x + \theta_j) : |\alpha_j| \leq 2C, y_j \in \mathbb{R}^n, \right. \\
\left. \theta_j \in \mathbb{R}, j = 1, 2, ..., N, \right. \\
\text{and} \left[ y_{(i-1)n+1} | y_{(i-1)n+2} | \cdots | y_{in} \right] \\
is an LDR matrix, \forall i = 1, ..., k \}. 
\] (3.2.4)

Moreover, let \(G_{\sigma}^k\) be the set of functions that can be expressed as a sum of no more than \(k\) terms from \(G_{\sigma}\). Define the metric

\[
||f - g||_\mu = \sqrt{\int_{B_r} (f(x) - g(x))^2 \mu(dx)}. 
\]

Theorem 3.2.1 essentially states that the minimal distance between a function \(f \in \Gamma_{C, B}\) and \(G_{\sigma}^m\) is asymptotically \(O(1/n)\). The following lemma proves that \(G_{\sigma}^k\) is in fact contained in \(S_{\sigma}^{kn}\).

**Lemma 3.2.1.** For any \(k \geq 1\), \(G_{\sigma}^k \subset S_{\sigma}^{kn}\).

**Proof.** Any function \(f_k(x) \in G_{\sigma}^k\) can be written in the form

\[
f_k(x) = \sum_{j=1}^{k} \alpha_j \sigma(y_j^T x + \theta_j). 
\] (3.2.5)

For each \(j = 1, ..., k\), define a \(n \times n\) LDR matrix \(W_j\) such that one of its column is \(y_j\). Let \(t_{ij}\) be the \(i\)-th column of \(W_j\). Let \(i_j\) correspond to
the column index such that $t_{ij} = y_j$ for all $j$. Now consider the following function,

$$G(x) := \sum_{j=1}^{k} \sum_{i=1}^{n} \beta_{ij} \sigma(t_{ij}^T x + \theta_j),$$

(3.2.6)

where $\beta_{ij}$ equals $\alpha_j$, and $\beta_{ij} = 0$ if $i \neq i_j$. Notice that we have the following equality,

$$G(x) := \sum_{j=1}^{k} \sum_{i=1}^{n} \beta_{ij} \sigma(t_{ij}^T x + \theta_j)$$

$$= \sum_{j=1}^{k} \beta_{i_jj} \sigma(t_{i_jj}^T x + \theta_j)$$

$$= \sum_{j=1}^{k} \alpha_j \sigma(y_j^T x + \theta_j) = f_k(x).$$

Notice that the matrix $W = [W_1 | W_2 | \cdots | W_k]$ consists of $k$ LDR submatrices. Thus $f_k(x)$ belongs to the set $S_{\sigma}^{kn}$. \hfill \Box

By Lemma 3.2.1, we can replace $G_{\sigma}^k$ with $S_{\sigma}^{kn}$ in Theorem 3.2.1 and obtain the following error bound estimates on LDR neural networks:

**Theorem 3.2.2.** For every disk $B_r \subset \mathbb{R}^n$, every function in $\Gamma_{C,B_r}$, every sigmoidal function $\sigma$, every normalized measure $\mu$, and every $k \geq 1$, there exists a neural network defined by a weight matrix consisting of $k$ LDR submatrices such that

$$\int_{B_r} (f(x) - f_{kn}(x))^2 \mu(dx) \leq \frac{4r^2C}{k}.$$  

(3.2.7)
Moreover, the coefficients of the linear combination may be restricted to satisfy
\[ \sum_{k=1}^{N} |c_k| \leq 2rC. \]

Since an \( n \times n \) LDR matrix can be defined by \( O(n) \) parameters, the space
requirement of storing a matrix with \( n \times kn \) LDR matrix is asymptotically the
same as that of an \( n \times k \) dense matrix. Since each \( n \times n \) LDR matrix with
displacement rank 1 can be determined by \( 2n \) parameters, function \( f_{kn} \) is
defined by \( 2kn \) parameters, which is asymptotically the same with a classical
neural network function defined by an \( n \times k \) dense matrix.

The next theorem naturally extends the result from [12] to LDR neural
networks, implying that LDR neural networks can benefit from parameter
reduction if one uses more than one layers. More precisely, we have the
following statement:

**Theorem 3.2.3.** Let \( f \) be a continuous function on \([0, 1]\) and is \( 2n+1 \) times
differentiable in \((0, 1)\) for \( n = \lceil \log \frac{1}{\epsilon} + 1 \rceil \). If \( |f^{(k)}(x)| \leq k! \) holds for all
\( x \in (0, 1) \) and \( k \in [2n+1] \), then for any \( n \times n \) matrices \( A \) and \( B \) satisfying
the conditions of Theorem 3.1.1, there exists a LDR neural network \( G_{A,B}(x) \)
with \( O(\log \frac{1}{\epsilon}) \) layers, \( O(\log \frac{1}{\epsilon} n) \) binary step units, \( O(\log^2 \frac{1}{\epsilon} n) \) rectifier linear
units such that

\[
\max_{x \in (0,1)} |f(x) - G_{A,B}(x)| < \epsilon.
\]
**CHAPTER 3. LDR NEURAL NETWORK**

**Proof.** The theorem with better bounds and without assumption of being LDR neural network is proved in [12] as Theorem 4. For each binary step unit or rectifier linear unit in the construction of the general neural network, attach \((n - 1)\) dummy units, and expand the weights associated to this unit from a vector to an LDR matrix based on Theorem 3.1.1. By doing so we need to add a factor \(n\) to the original amount of units, and the asymptotic bounds are relaxed accordingly. \(\square\)

### 3.3 Training LDR Neural Networks

In this section, we reformulate the gradient computation of LDR neural networks. The computation for propagating through a fully-connected layer can be written as

\[
y = \sigma(W^T x + \theta),
\]

where \(\sigma(\cdot)\) is the activation function, \(W \in \mathbb{R}^{n \times kn}\) is the weight matrix, \(x \in \mathbb{R}^n\) is input vector and \(\theta \in \mathbb{R}^{kn}\) is bias vector. According to Equation (7), if \(W_i\) is an LDR matrix with operators \((A_i, B_i)\) satisfying conditions of Theorem 3.1.1, then it is essentially determined by two matrices \(G_i \in \mathbb{R}^{n \times r}, H_i \in \mathbb{R}^{n \times r}\) as

\[
W_i = \left[ \sum_{k=0}^{q-1} A_{i}^{k}G_{i}H_{i}^{T}B_{i}^{k} \right](I - aB_{i}^{q})^{-1}.
\]
To fit the back-propagation algorithm, our goal is to compute derivatives \( \frac{\partial O}{\partial G} \), \( \frac{\partial O}{\partial H} \), and \( \frac{\partial O}{\partial x} \) for any objective function \( O = O(W_1, \ldots, W_k) \).

In general, given that \( a := W^T x + \theta \), we have:

\[
\frac{\partial O}{\partial W} = x \left( \frac{\partial O}{\partial a} \right)^T, \quad \frac{\partial O}{\partial x} = W \left( \frac{\partial O}{\partial a} \right), \quad \frac{\partial O}{\partial \theta} = \left( \frac{\partial O}{\partial a} \right) 1. \quad (3.3.3)
\]

Here \( 1 \) is a column vector full of ones. Let \( \hat{G}_{ik} := A_i G_i, \hat{H}_{ik} := H_i^T B_i^k (I - aB_i^q)^{-1} \), and \( W_{ik} := \hat{G}_{ik} \hat{H}_{ik} \). The derivatives of \( \frac{\partial O}{\partial W_{ik}} \) can be computed as following:

\[
\frac{\partial O}{\partial W_{ik}} = \frac{\partial O}{\partial W_i}. \quad (3.3.4)
\]

According to Equation (3.3.3), if we let \( a = W_{ik}, W = \hat{G}_{ik}^T \) and \( x = \hat{H}_{ik} \), then \( \frac{\partial O}{\partial G_{ik}} \) and \( \frac{\partial O}{\partial H_{ik}} \) can be derived as:

\[
\frac{\partial O}{\partial \hat{G}_{ik}} = \left[ \frac{\partial O}{\partial \hat{G}_{ik}^T} \right]^T = \left[ \hat{H}_{ik} \frac{\partial O}{\partial W_{ik}} \right]^T = \left( \frac{\partial O}{\partial W_{ik}} \right)^T \hat{H}_{ik}^T, \quad (3.3.5)
\]

\[
\frac{\partial O}{\partial \hat{H}_{ik}} = \hat{G}_{ik}^T \frac{\partial O}{\partial W_{ik}}. \quad (3.3.6)
\]

Similarly, let \( a = \hat{G}_{ik}, W = (A_i^k)^T \) and \( x = G_i \), then \( \frac{\partial O}{\partial A_i} \) can be derived as:

\[
\frac{\partial O}{\partial A_i} = \sum_{k=0}^{q-1} (A_i^k)^T \left( \frac{\partial O}{\partial \hat{G}_{ik}} \right) = \sum_{k=0}^{q-1} (A_i^k)^T \left( \frac{\partial O}{\partial W_{ik}} \right)^T \hat{H}_{ik}^T. \quad (3.3.7)
\]
Substituting with $\mathbf{a} = \mathbf{\hat{H}}_{ik}$, $\mathbf{W} = \mathbf{H}_i^T$ and $\mathbf{x} = \mathbf{B}_i^k(\mathbf{I} - \mathbf{a}\mathbf{B}_i^q)^{-1}$, we have $\frac{\partial O}{\partial \mathbf{H}_i}$ derived as:

$$
\frac{\partial O}{\partial \mathbf{H}_i} = \sum_{k=0}^{q-1} \mathbf{B}_i^k(\mathbf{I} - \mathbf{a}\mathbf{B}_i^q)^{-1} \left( \frac{\partial O}{\partial \mathbf{\hat{H}}_{ik}} \right)^T = \sum_{k=0}^{q-1} \mathbf{B}_i^k(\mathbf{I} - \mathbf{a}\mathbf{B}_i^q)^{-1} \left( \frac{\partial O}{\partial \mathbf{W}_i^k} \right)^T \mathbf{G}_{ik}, \quad (3.3.8)
$$

In this way, derivatives $\frac{\partial O}{\partial \mathbf{G}_i}$ and $\frac{\partial O}{\partial \mathbf{H}_i}$ can be computed given $\frac{\partial O}{\partial \mathbf{W}_i}$, equal to $\frac{\partial O}{\partial \mathbf{W}_i}$. The essence of back-propagation algorithm is to propagate gradients backward from the layer with objective function to the input layer. $\frac{\partial O}{\partial \mathbf{W}_i}$ can be calculated from previous layer and $\frac{\partial O}{\partial \mathbf{x}}$ will be propagated to the next layer if necessary.

In practice one may choose matrices $\mathbf{A}_i$ and $\mathbf{B}_i$ that can be multiplied by a vector fast, for example, diagonal matrices, permutation matrices, banded matrices, etc. Then the space complexity (the number of parameters for storage) of $\mathbf{W}_i$ can be $O(2n + 2nr)$ rather than $O(n^2)$ in the case of usual dense matrix. The term $2n$ is associated with $\mathbf{A}_i$ and $\mathbf{B}_i$ and the term $2nr$ with $\mathbf{G}_i$ and $\mathbf{H}_i$. The time complexity of $\mathbf{W}_i^T \mathbf{x}$ is $O(q(3n + 2nr))$ compared with $O(n^2)$ of dense matrix. Particularly, when $\mathbf{W}_i$ is a structured, e.g., Toeplitz matrix, the space complexity will be $O(2n)$. This is because the Toeplitz matrix is defined by $2n$ parameters. Moreover, its matrix-by-vector multiplication can be accelerated by using Fast Fourier Transform (for Toeplitz and circulant matrices).
matrices), resulting in time complexity $O(n \log n)$. In this way the back-propagation computation for the layer can be done in nearly linear time.

### 3.4 Conclusion

In this chapter, we have proven the universal approximation property of LDR neural networks. In addition, we also theoretically show that the error bounds of LDR neural networks are at least as efficient as in the case of general unstructured neural network. Besides, we also develop the back-propagation based training algorithm for universal LDR neural networks. Our study provides some theoretical foundation for the empirically observed success of the application of the LDR neural networks.

Chapter 4
Gaussian Elimination without Pivoting

4.1 BGE and GENP

For a nonsingular $2 \times 2$ block matrix $A = \begin{pmatrix} B & C \\ D & E \end{pmatrix}$ of size $n \times n$ with nonsingular $k \times k$ pivot block $B = A_{k,k}$, define $S = S(A_{k,k}, A) = E - DB^{-1}C$, the Schur complement of $A_{k,k}$ in $A$, and the block factorizations,

$$A = \begin{pmatrix} I_k & O_{k,r} \\ DB^{-1} & I_r \end{pmatrix} \begin{pmatrix} B & O_{k,r} \\ O_{r,k} & S \end{pmatrix} \begin{pmatrix} I_k & B^{-1}C \\ O_{k,r} & I_r \end{pmatrix} \quad (4.1.1)$$

and

$$A^{-1} = \begin{pmatrix} I_k & -B^{-1}C \\ O_{k,r} & I_r \end{pmatrix} \begin{pmatrix} B^{-1} & O_{k,r} \\ O_{r,k} & S^{-1} \end{pmatrix} \begin{pmatrix} I_k & O_{k,r} \\ -DB^{-1} & I_r \end{pmatrix}. \quad (4.1.2)$$

We verify readily that $S^{-1}$ is the $(n-k) \times (n-k)$ trailing (that is, southeastern) block of the inverse matrix $A^{-1}$, and so the Schur complement $S$ is nonsingular since the matrix $A$ is nonsingular.
Factorization (4.1.2) reduces the inversion of the matrix $A$ to the inversion of the leading block $B$ and its Schur complement $S$, and we can recursively reduce the inversion task to the case of the leading blocks and Schur complements of decreasing sizes as long as the leading blocks are nonsingular. After sufficiently many recursive steps of this process of BGE, we only need to invert matrices of small sizes, and then we can stop the process and apply a selected black box inversion algorithm, e.g., based on orthogonalization.

In $\lceil \log_2(n) \rceil$ recursive steps all pivot blocks and all other matrices involved into the resulting factorization turn into scalars, all matrix multiplications and inversions turn into scalar multiplications and divisions, and we arrive at a complete recursive factorization of the matrix $A$. If $k = 1$ at all recursive steps, then the complete recursive factorization (4.1.2) defines GENP.

Moreover, any complete recursive factorizations turns into GENP up to the order in which we consider its steps. This follows because at most $n - 1$ distinct Schur complements $S = S(A_{k,k}, A)$, for $k = 1, \ldots, n - 1$, are involved in all recursive block factorization processes for $n \times n$ matrices $A$, and so we arrive at the same Schur complement in a fixed position via GENP and via any other recursive block factorization (4.1.1). Hence we can interpret factorization step (4.1.1) as the block elimination of the first $k$ columns of the matrix $A$, which produces the matrix $S = S(A_{k,k}, A)$. If the dimensions
CHAPTER 4. GAUSSIAN ELIMINATION WITHOUT PIVOTING

d_1, \ldots, d_r \text{ and } \bar{d}_1, \ldots, \bar{d}_r \text{ of the pivot blocks in two block elimination processes sum to the same integer } k, \text{ that is, if } k = d_1 + \cdots + d_r = \bar{d}_1 + \cdots + \bar{d}_r, \text{ then both processes produce the same Schur complement } S = S(A_{k,k}, A). \text{ The following results extend this observation.}

Theorem 4.1.1. In the recursive block factorization process based on (4.1.1), the diagonal block and its Schur complement in every block diagonal factor is either a leading block of the input matrix A or the Schur complement \( S(A_{h,h}, A_{k,k}) \) for some integers \( h \) and \( k \) such that \( 0 < h < k \leq n \) and \( S(A_{h,h}, A_{k,k}) = (S(A_{h,h}, A))_{h,h}. \)

Corollary 4.1.1. The recursive block factorization process based on equation (4.1.1) can be completed by involving no singular pivot blocks (and, in particular, no pivot elements vanish) if and only if the input matrix A is strongly nonsingular.

Proof. Combine Theorem 4.1.1 with the equation \( \det A = (\det B) \det S, \text{ implied by (4.1.1)}. \)

Remark 4.1.1. Applying BGE (unike GENP) we can use the benefits of block matrix algorithms.

Remark 4.1.2. One can benefit from application of BGE to computations with structured matrices. E.g., the MBA superfast algorithm, by Morf [M74],
[M80] and by Bitmead and Anderson [BA80], runs in nearly linear arithmetic time in the case of Toeplitz and Toeplitz-like inputs. This algorithm is precisely the recursive BGE, accelerated by means of exploiting the Toeplitz-like structure of the input matrix extended throughout the recursive process of BGE (cf. Remark 4.3.1). The algorithm has been further extended to computations with structured matrices of other classes [P01, Chapter 5].

4.2 Preprocessing for GENP and BGE

In this section, $A$ denotes a nonsingular $n \times n$ matrix.

Suppose that the vector $y = Ab$ satisfies pre-processed linear systems $AHy = b$ and $FAH y = Fb$. Then the vector $x = Hy$ satisfies the linear system $Ax = b$ as well as the pre-processed linear system $FAx = Fb$. Next we estimate the efficiency of preprocessing for GENP and BGE with random and fixed post-multipliers $H$. Our analysis is immediately extended to preprocessings $A \rightarrow FA$, $A \rightarrow FAH$, and $A \rightarrow FAF^H$.

One can verify by action whether a fixed preprocessing works, by testing whether pre-processed GENP or BGE solves a linear system of equations $Ax = b$, but for probabilistic analysis we proceed in circuited ways, based on Theorem 4.1.1 and Corollary 4.1.1.
4.2.1 Basic definitions and auxiliary results

We call GENP and BGE \emph{safe} if they proceed to the end with no divisions by 0.

Corollary 4.1.1 implies the following result for computations in any field.

\textbf{Theorem 4.2.1.} \textit{GENP is safe if and only if the input matrix is strongly nonsingular.}

Next assume that GENP and BGE are performed numerically, with rounding to a fixed precision, e.g., the IEEE standard double precision. Then extend the concept of safe GENP and BGE to \textit{numerically safe GENP and BGE} by requiring that the input matrix be strongly nonsingular and \textit{strongly well-conditioned}, that is, that the matrix itself and all its square leading blocks be nonsingular and well-conditioned (cf. item 1.4.13).

Any inversion algorithm for a nonsingular matrix is highly sensitive to both input and rounding errors if and only if the matrix is ill-conditioned \cite{GL13}, and likewise GENP is highly sensitive to the input and rounding errors if and only if some of the square leading blocks are ill-conditioned (see \cite[PQZ13, Theorem 5.1]{PQZ13} for quantitative version of these statements).

\textbf{Remark 4.2.1.} \textit{BGE is safe if so does GENP. Likewise BGE is safe numerically if so does GENP. Thus our proofs of safety and numerical safety
of GENP apply to BGE. The converse is not true, however. GENP fails (resp. fails numerically) if any leading square block of the input matrix is singular (resp. ill-conditioned), but BGE may by-pass this block and be safe (resp. numerically safe).

4.2.2 GENP with Gaussian preprocessing is likely to be numerically safe

Suppose that a nonsingular and well-conditioned matrix $A$ has been preprocessed with a Gaussian multiplier $H$. Let us prove that the products $FA$ and $AH$ are likely to be numerically safe for GENP and BGE, in good accordance with the results of our tests reported in Section 4.5.

**Theorem 4.2.2.** (Cf. [PQY15, Corollary 5.2].)

Assume that we are given a nonsingular and well-conditioned $n \times n$ matrix $A$ and a pair of $n \times n$ Gaussian matrices $F$ and $H$. Then

(i) the matrices $FA$ and $AH$ are strongly nonsingular with a probability $1$,

\[ \max_{k=1}^{n} \{ \|(AH)_{k,k}\|, \|(FA)_{k,k}\| \} \leq \nu_{n,k}^{+} / \sigma(A) = \nu_{n,k}^{+} ||A^{+}|| \]

for $\nu_{n,k}^{+}$ of Appendix A (cf. items 1.4.2, 1.4.4, and 1.4.9).

**Proof.** The proof is similar for both products $AH$ and $FA$; we only cover the case of the former one.
PART (i) follows from part (ii) of Theorem A.1.1 applied for $H = G$.

To prove part (ii), note that $(AH)_{k,k} = A_{k,n} H_{n,k}$, substitute SVD $A_{k,n} = S_{k,n} \Sigma T^T$ (cf. items 1.4.2 and 1.4.9), and obtain $(AH)_{k,k} = S_{k,n} \Sigma T^T H_{n,k} = S_{k,n} \Sigma G_{n,k}$ where $G_{n,k} = T^T H_{n,k}$ is an $n \times k$ Gaussian matrix by virtue of Lemma A.2.1 because $H_{n,k}$ is a Gaussian matrix and the matrix $T$ is orthogonal. It follows that $((AH)_{k,k})^+ = G^+_{n,k} \Sigma^{-1} S^T_{k,n}$ (cf. item 1.4.5). Hence $||(AH)_{k,k}||^+ = ||G^+_{n,k} \Sigma^{-1}|| \leq ||G^+_{n,k}|| ||\Sigma^{-1}||$ because the matrix $S_{k,n}$ is orthogonal. Substitute the equations $||G^+_{n,k}|| = \nu^+_{n,k}$ and $||\Sigma^{-1}|| = 1/\sigma_n(A) = ||A^+||$ (cf. items 1.4.7 and 1.4.11).

Theorems 4.2.2, A.2.1, and A.2.2 together imply the following primal and dual results (i) and (ii).

Corollary 4.2.1. (i) Suppose GENP and BGE have been applied to a matrix $A$ pre-processed with a Gaussian multiplier $F$ or $H$ or with a pair of Gaussian multipliers $F$ and $H$. Then these algorithms are safe with probability 1 if and only if the matrix $A$ is nonsingular. Moreover they are likely to be also numerically safe if this matrix is nonsingular and well-conditioned.

(ii) GENP and BGE are safe and numerically safe when they are applied to average input matrix defined under the Gaussian probability distribution and pre-processed with any fixed nonsingular and well-conditioned multiplier.
Remark 4.2.2. The upper estimates of Theorem A.2.2 for $\nu_{n,k}$ are strengthened dramatically as the integer $n - k$ increases. Hence we can strengthen numerical safety of recursive BGE by stopping the recursive process when it reduces the factorization task to the inversion of matrices of size $h \times h$ for a fixed small positive $h$, say, $h = 4$. Then we can invert these matrices of small size with no numerical problems and at a low computational cost, e.g., by applying orthogonalization. We call this technique incomplete BGE. Likewise, we can stop GENP when we reduce the factorization task to the case of $h \times h$ matrix, then apply orthogonalization, and arrive at incomplete GENP.

4.2.3 Recursive block preprocessing for GENP

We can pre-process an $n \times n$ input matrix with Gaussian multipliers by using fewer random parameters and arithmetic operations if we proceed recursively. At first pre-process the $k \times k$ leading block of the input matrix for a proper integer $k < n$ by using $n \times k$ Gaussian multipliers. Having factored this block, we decrease the input size from $n$ to $n - k$, and then we can re-apply Gaussian preprocessing. Already by using such a two-step block preprocessing for $k = n/2$, we save 1/4 of all random parameters and 3/8 of arithmetic operations involved, but this also yields an additional benefit. Namely, recall the bound $\|((AG)_{k,k})^+\| \leq \nu^+_{n,k}/\sigma_n(A)$ of part (ii) of Theorem 4.2.2 for the $k \times k$ leading
block of an input matrix $A$. The factor $1/\sigma_n(A)$ on the right-hand side is fixed for all $k$, but the factor $\nu_{n,k}^+$ is expected to decrease fast as $k$ decreases from $n$, implying smaller expected residual norm of the output approximation.

One can apply this recipe to the case where $k = n - 4$, say, and then solve the remaining linear system of four equations by applying some numerically stable methods, e.g., based on orthogonalization (cf. Remark 4.2.2).

4.2.4 Choice of multipliers. Universal sets of multipliers. Random versus fixed multipliers. Random universal sets

If we fix a nonsingular and well-conditioned multiplier $H$, then part (ii) of Corollary 4.2.1 implies that GENP and BGE are safe and numerically safe for most of nonsingular and well-conditioned input matrices $A$. This applies even to $H = I_n$, that is, to GENP and BGE with no preprocessing.

For any fixed multiplier $H$, however, there exist bad nonsingular and well-conditioned input matrices $A$, such that GENP and BGE are unsafe or numerically unsafe for the input $AH$. Such a bad matrix $A$ can be a typical input of some actual computations, but by virtue of Corollary 4.2.1, a nonsingular and well-conditioned input can be bad only for a small fraction of all multipliers.

This suggests the following policy of testing a family of multipliers by
action for a fixed input: successively or concurrently apply multipliers from this family (and possibly also vary the policy of pre-, post- and two-sided preprocessing) and stop as soon as you succeed in any of these applications, that is, when you observe a small relative residual norm $||Ax - b||/||(A \mid x)||$ or a small value of the growth factor in the LU factorization of the matrix $FA, AH, FAH$, or $FAF^H$.

Can we choose a small universal set of multipliers, with which such a test would succeed for any input? Clearly, we are motivated to choose structured or sparse multipliers such that we can generate them and multiply them by an input matrix at a low cost. Can we choose a small universal set made up of sparse and structured multipliers? So far even the problem of constructing any small universal set of multipliers is open.

By virtue of part (i) of Corollary 4.2.1, we would succeed with a probability close to 1 for any input if we choose a random multiplier from a family of all matrices under the Gaussian probability distribution, and so such a family is a random universal set of multipliers. This set is not small, however, its multipliers are not sparse or structured, and the above problems remain open even if, instead of fixing a multiplier, we allow to choose it at random from a fixed small family of matrices.

In Sections 4.3.5, 4.4, and ??, we present our results about random univer-
sal sets made up of structured matrices, but right away we note the following
dilemma of random versus fixed preprocessing for such sets: which highly
unlikely failure should the user try to avoid more – with random (e.g., Gaus-
sian) or fixed preprocessing? Indeed, for actual computations, the user can
be satisfied with non-universal preprocessing as long as it covers the input
sets of interest.

4.3 Some classes of structured multipliers

4.3.1 What kind of multipliers do we seek?

We seek multipliers $F$ and $H$ that support both safety and numerical safety
of GENP, and according to Remark 4.2.1, their support for GENP can always
be readily extended to BGE.

1. Multipliers $F$ and $H$ must be nonsingular and well-conditioned.

2. The relative residual norm of the output should be small when GENP
   is applied to a pre-processed matrix.

3. The cost of the computation of the product $FA$, $AH$, $FAH$ or $FAFH$
   should be small.

4. Random multipliers should be generated by using fewer random pa-
   rameters, and properties 1 and 2 are only required for them with a
5. In the case of structured input matrices, the multipliers should have consistent structure.

4.3.2 Structured multipliers for safe GENP

If we only require safety of GENP, but not necessarily its numerical safety, then our requirements 1 and 2 to the multipliers can be softened accordingly.

Randomized multipliers that support safe GENP and BGE with probability 1, for any nonsingular input, have been found already in 1991 and covered in [BP94, Section 2.13]. Among them one-sided preprocessing with random Toeplitz multipliers of [KP91] is most efficient, but slightly inferior two-sided preprocessing with random triangular Toeplitz multipliers of [KS91] has become most popular.

In Section 4.4, we prove that even random circulant multipliers, involving fewer flops and random parameters (see Appendix C and [P01] for definitions) ensure safe GENP and BGE with probability 1 under Gaussian choice of these parameters or with a probability close to 1 under their uniform choice from a large set. Using circulant multipliers saves 50% of random parameters and enables a 4-fold (resp. 2-fold) acceleration of the preprocessing of [KS91] (resp. [KP91]).
4.3.3 Circulant multipliers

A circulant multiplier $H$ is defined by the $n$ entries of its first column, and then the computation of the product $AH$ is reduced essentially to performing $3n$ FFTs at the $n$th roots of 1. This involves about $4.5n^2 \log(n)$ flops, for a general matrix $A$. In modern computational practice such a cost bound can still be dominated by the cost of pivoting. Furthermore parallel implementation of FFT is known to be highly efficient, in particular, when it is based on Application Specific Integrated Circuits (ASICs) and Field-Programmable Gate Arrays (FPGAs), incorporating Butterfly Circuits [DE]. Moreover, in the important case of Toeplitz or Toeplitz-like matrix $A$ and a circulant multiplier $H$, we can compute a standard displacement representation of the product $AH$ by applying just $O(n \log(n))$ flops (cf. [P01]).

Thus the random circulant multipliers satisfy requirement 1 above with a probability close to 1 (according to Remarks C.0.2 and C.0.3). They also satisfy requirements 3 and 4 (see Corollary C.0.1) as well as requirement 5 for the matrix structure of Toeplitz type. Empirically they also satisfy requirement 2. This suggests that random circulant multipliers are good candidates also for supporting numerical GENP and BGE.

**Remark 4.3.1.** (Cf. Remark 4.1.2.) In the presence of rounding errors,
the MBA algorithm fails except for the inputs of small size because of severe numerical problems [B85], while pivoting is not an option for solving Toeplitz or Toeplitz-like linear systems of equations because it destroys the matrix structure. So preprocessing is badly needed in this case. Fortunately, preprocessing with appropriate randomized structured multipliers is likely to fix these problems, and similarly in the extensions of the MBA algorithm to computations with other structured matrices (cf. [P01, Sections 5.6 and 5.7]). In particular, random circulant multiplication keeps Toeplitz structure intact (cf. [P01, Chapters 4 and 5]), and the computation of a standard displacement representation of the product of a Toeplitz or Toeplitz-like $n \times n$ matrix by a circulant matrix only requires $O(n \log(n))$ arithmetic operations (cf. [P01]) or just $O(n)$ multiplications if the circulant matrices involved are represented by using the factorization of Theorem C.0.1.

4.3.4 Structured multipliers from the study of low-rank approximation

As we are going to see in Section 2.4.3, multipliers for GENP and BGE work similarly to the ones for low-rank approximation of a matrix. Next we accommodate for GENP some efficient structured multipliers developed for the latter task in the last decade.

This includes subsample random Hadamard transforms (hereafter SRHT),
subsample random Fourier transforms (hereafter SRFT), and the chains of random Givens rotations (see [HMT11, Sections 4.6 and 11] and [M11]). All of them are unitary up to scaling. In applications to low-rank approximation, they are $n \times l$ rectangular matrices where $l \leq n$, and typically $l \ll n$, but in application to GENP and BGE they are square matrices. These multipliers are represented as the products of basic matrices $P$, $C$, and $D$ defined separately for each family of multipliers. Here $P$ is a (random or fixed) permutation matrix, $D$ is a (random or fixed) diagonal matrix (and so each matrix $P$ or $D$ has $n$ nonzero entries), and $C$ is a core matrix.

SRHT and SRFT multipliers are represented as the products $DCP$. Multipliers based on the chains of random Givens rotations are represented as the products

$$C = D''P''C'D'P'C\Omega_nP. \quad (4.3.1)$$

Here the prime symbol $'$ indicates independent realization of a matrix, and here and hereafter $\Omega_n = (\omega_{ij})_{i,j=0}^{n-1}$ is the $n \times n$ matrix of discrete Fourier transform, DFT($n$), where $n = 2^k$, for an integer $k \geq 0$, and $\omega = \omega_n = \exp(2\pi\sqrt{-1}/n)$ is a primitive $n$th root of 1 (cf. Definition B.0.1). Scaling by $1/\sqrt{n}$ preserves the condition number of the matrix $\Omega_n$ and turns it into a unitary matrix (cf. items 1.4.5 and 1.4.11).
CHAPTER 4. GAUSSIAN ELIMINATION WITHOUT PIVOTING

Remark 4.3.2. Instead of the complex matrix DFT\((n)\), one can consider the real matrices of the sine, cosine or Hartley transforms (cf. [P01, Section 3.11]).

Next we specify the core matrices for multipliers based on SRHT, SRFT, and equation (4.3.1).

In the case of an SRHT multiplier, \(C = H_k\) is the matrix of Hadamard transform, also called Walsh–Hadamard transform. Next we define it recursively, for any pair of integers \(d \geq 1\) and \(k \geq d\). This generalizes the customary recursive definition, in which \(d = k\):

\[
H_j = \begin{pmatrix} H_{j-1} & H_{j-1} \\ H_{j-1} & -H_{j-1} \end{pmatrix}, \quad j = k, k-1, \ldots, k-d+1; \quad H_{k-d} = \begin{pmatrix} I_{2k-d} & I_{2k-d} \\ I_{2k-d} & -I_{2k-d} \end{pmatrix}.
\]

(4.3.2)

In the case of an SRFT multiplier, \(C\) is the \(n \times n\) matrix \(\Omega_n\) of DFT\((n)\) where \(n = 2^k\), for an integer \(k \geq 0\), but next we define that matrix recursively, similarly to equation (4.3.2), for any pair of integers \(d \geq 1\) and \(k \geq d\). This generalizes the customary recursive definition in which \(d = k\) (cf. [P01, equation 2.3.1]):

\[
\Omega_{2^j} = P_j \text{ diag}(\Omega_{2^{j-1}}, \Omega_{2^{j-1}}) \text{ diag}(I_{2^{j-1}}, D_j) \begin{pmatrix} I_{2^{j-1}} & I_{2^{j-1}} \\ I_{2^{j-1}} & -I_{2^{j-1}} \end{pmatrix}.
\]

(4.3.3)

Here \(P_j\) is the \(2^j \times 2^j\) odd/even permutation matrix, such that \(P_{2^s}(u) = v\), \(u = (u_i)_{i=0}^{2s-1}\), \(v = (v_i)_{i=0}^{2s-1}\), \(v_i = u_{2i}\), \(v_{i+s} = u_{2i+1}\), \(i = 0, 1, \ldots, s - 1\), and
CHAPTER 4. GAUSSIAN ELIMINATION WITHOUT PIVOTING

\[ D_{2s} = \text{diag}(\omega_{2s}^j)_{j=0}^{s-1}. \]

A core matrix of any of the two classes SRHT and SRFT can be multiplied by a vector by using \( O(n \log(n)) \) flops.

In the case of the chains of random Givens rotations of (4.3.1),

\[ C = G(1, 2, \theta_1)G(2, 3, \theta_2) \cdots G(n - 1, n, \theta_{n-1}), \quad (4.3.4) \]

and \( G(i, j, \theta) \) is the matrix of Givens rotation on \( \mathbb{C}^n \) by the angle \( \theta \) in the \((i, j)\) coordinate plane (cf. [GL13]). This core matrix can be multiplied by a vector by using \( O(n) \) flops, but multiplication by a vector of the factor \( \Omega \) in equation (4.3.1) involves order of \( n \log(n) \) flops.

4.3.5 Numerical GENP with structured multipliers: bad inputs

Randomized versions of the multipliers of the previous section are random universal for the task of low-rank approximation, but not for supporting GENP. We have proved randomized universality of Gaussian multipliers for the latter task, but cannot extend the proof to any family of sparse and structured multipliers. Moreover, next we specify some inputs for which GENP fails numerically if it is not pre-processed at all or if it is pre-processed with any circulant or SRFT multiplier.

At first recall from [Pa] that GENP is numerically unsafe for the \( n \times n \)
CHAPTER 4. GAUSSIAN ELIMINATION WITHOUT PIVOTING

unitary matrix $A = \frac{1}{\sqrt{n}} F$ and consequently for the inverse matrix $A^{-1} = \frac{1}{\sqrt{n}} \Omega^H_n$ as well, provided that $n$ is a large integer and $\Omega_n$ denotes the matrix DFT$(n)$ of discrete Fourier transform (which is unitary up to scaling by $1/\sqrt{n}$). Of course, one does not need to apply GENP in order to invert these matrices, but by extending this result of [Pa], we specify some hard inputs for numerical application of GENP pre-processed with any fixed circulant multiplier and consequently with a Gaussian circulant multiplier.

The proof in [Pa] can be readily extended to the matrices $U_f, \Omega_n R, R^H \Omega^H_n, U_f R,$ and $R^H U^H_f,$ for a complex $f$ such that $|f| = 1,$ the matrix $U_f$ of Theorem C.0.1, and a unitary (e.g., permutation) matrix $R.$ Next, based on these results, we prove that GENP is numerically unsafe also if it is pre-processed with some structured matrices of large sizes.

**Theorem 4.3.1.** Assume that we are given a large integer $n,$ a complex $f$ such that $|f| = 1,$ the $n \times n$ DFT matrix $\Omega = \Omega_n,$ an $n \times n$ unitary (e.g., permutation) matrix $R,$ and a circulant $n \times n$ matrix $Z_f(v) = \Omega^{-1} D \Omega$ with diagonal matrix $D = \text{diag}(g_j)_{j=1}^n.$ Write $U_f = \Omega D(f)$ for $D(f)$ of Theorem C.0.1. Then application of GENP to the matrices $\Omega Z_f(v), \Omega Z_f(v) R,$ $Z_f(v) \Omega^H, R^H Z_f(v) \Omega^H, U_f Z_f(v), U_f Z_f(v) R,$ $Z_f(v) U^H_f,$ and $R^H Z_f(v) U^H_f$ is numerically unsafe.
Proof. At first recall that $\Omega Z_1(v) = D\Omega$, by virtue of Theorem C.0.1, and that $(D\Omega)_{k,k} = D_{k,k}\Omega_{k,k}$. Then recall from [Pa] that GENP applied to the matrix $\Omega$ fails numerically, which occurs because there is a singular or ill-conditioned leading block $\Omega_{k,k}$ of the matrix $\Omega$.

If the diagonal matrix $D$ is nonsingular and well-conditioned, then so are its leading block $D_{k,k}$, and hence the block $(D\Omega)_{k,k} = D_{k,k}\Omega_{k,k}$ as well, because so is the matrix $\Omega_{k,k}$.

If the matrix $D_{k,k}$ is singular or ill-conditioned, then so are the matrices $D$ and $D\Omega$ as well because $\Omega$ is a unitary matrix (up to scaling by $1/\sqrt{n}$).

Up to scaling by a constant, the matrix $D \Omega R$, for a random permutation matrix $R$, is an $n \times n$ SRFT matrix from [HMT11, Sections 4.6 and 11.1], whose $n \times l$ and $l \times n$ blocks are extensively used in various randomized matrix computations, for $l < n$ and usually for $l \ll n$. Theorem 4.3.1 shows that GENP with an $n \times n$ SRFT multiplier is likely to fail numerically already for the identity input matrix.

4.3.6 Some simplified multipliers

By virtue of part (ii) of Corollary 4.2.1, even non-universal multipliers satisfying requirements 1–5 of Section 4.3 can be valuable. Next we simplify the generation of the multipliers of the previous subsection and their multiplica-
CHAPTER 4. GAUSSIAN ELIMINATION WITHOUT PIVOTING

...tion by input matrices.

Actually there can be some tradeoff between low cost of preprocessing and output accuracy, but for all of our previous and next multipliers, a single refinement iteration was always sufficient in our tests in order to match or to exceed the output accuracy of GEPP (see also some empirical data in [PQZ13], [BDHT13], [DDF14], and [PQY15] and see [H02, Chapter 12], [GL13, Section 3.5.3], and the references therein for detailed coverage of iterative refinement). A refinement iteration involves $O(n^2)$ flops versus the dominant cubic cost of $\frac{2}{3}n^3$ flops, involved in Gaussian elimination, but for small $n$ quadratic cost of refinement can make up a large share of the overall cost. In our tests, however, preprocessing of GENP with most of our multipliers (unlike the PRBT multipliers of [BDHT13], [DDF14], and [BBBDD14]) achieved high output accuracy even without iterative refinement.

Next we describe some refined multipliers.

1. We can fill the first column $v$ of a circulant multiplier with 0s, except for a small number $\text{nz}(v)$ of its entries. Then we can compute the product $AH$ by using at most $(2\text{nz}(v) - 1)n$ flops. We have neither formal nor empirical support for numerical safety of GENP and BGE with this preprocessing alone, but empirically we do observe such support when...
preprocessing combines these and some other multipliers (cf. Table 4.5.6).

2. *Abridged SRHT multipliers* defined by equation (4.3.2) for a small positive integer $d$ (possibly even for $d = 1$) are simple to generate and can be multiply by a vector and by an input matrix by using $O(n)$ and $O(n^2)$ flops, respectively.

3. The same comments apply to *abridged SRFT multipliers* defined by equation (4.3.3) for a small positive integer $d$.

4. The multipliers defined by the chains of random Givens rotations of (4.3.1) are simplified similarly and in particular can be multiplied by a vector and an input matrix by using $O(n)$ and $O(n^2)$ flops, respectively, if in the definition by equation (4.3.1) we remove the factor $\Omega_n$ or replace it by its abridged version defined by equation (4.3.3) for $n = 2^k$ and a small positive integer $d$.

5. An interesting class of multipliers for recursive two-sided preprocessing, with *Partial Random Butterfly Transforms* (hereafter we use the acronym *PRBTs*), was proposed ad hoc in Technical Reports of 1995 by Parker and Parker and Pierce, which still remain unpublished (cf. [PP95]). These multipliers have been improved, carefully implemented,
and then extensively tested in the paper [BDHT13]. For an \( n \times n \) input matrix and for even \( n = 2k \), that paper defines PRBT as follows,

\[
B^{(n)} = \frac{1}{\sqrt{2}} \begin{pmatrix} R & S \\ R & -S \end{pmatrix} = \frac{1}{\sqrt{2}} \begin{pmatrix} I_k & I_k \\ I_k & -I_k \end{pmatrix} \text{diag}(R, S)
\] (4.3.5)

where \( R \) and \( S \) are random diagonal nonsingular matrices. The paper [BDHT13] defines multipliers \( F \) and \( H \) recursively by using PRBT blocks. According to [BDHT13], the two-sided recursive processes of depth \( d = 2 \) with PRBT blocks are “sufficient in most cases”. In such processes \( F = \text{diag}(B_1^{(n/2)}, B_2^{(n/2)})B^{(n)} \) and the multiplier \( H \) is defined similarly. In the case of depth-\( d \) recursion, \( d \geq 2 \), each of the multipliers \( F \) and \( H \) is defined as the product of \( d \) factors made up of \( 2^j \) diagonal blocks of size \( n/2^j \times n/2^j \), for \( j = 0, \ldots, d - 1 \), each block of the same type as above.

The PRBT recursive preprocessing of depth \( d \) involves \( 2dn \) random values, and the computation of the product \( FAH \) involves \( 5dn^2 \) flops. One needs just \( dn \) random values if \( F = H^T \). Saving flops is not of the highest importance because in computational practice pivoting typically costs even more than using \( n \times n \) circulant multipliers.

The PRBT-based preprocessing satisfies requirements 1, 3 and 4, listed in the beginning of this subsection, and empirically satisfies require-
ment 2 as well, but not requirement 5.

6. The left multipliers \((I_n + Z^T_{\pm})^{-1}\) and the right ones \((I_n + Z_{\pm})^{-1}\) where \(Z_{\pm}\) denote \(n \times n\) matrices filled with 0s, except for the \(n - 1\) entries of the first subdiagonal filled with the values \(\pm 1\). These multipliers satisfy requirements 1, 3, and 4 as well as requirement 2 (empirically) and requirement 5 for rank structured matrices \(A\) of [VVM07], [EGH13]. The computation of the product \(FAH\) involves less than \((n - 1)\text{nz}(A)\) additions and subtractions where \(\text{nz}(M)\) denotes the number of nonzero entries of the matrix \(M\), \(\text{nz}(M) \leq n^2\) for an \(n \times n\) matrix \(M\). Furthermore we estimate readily that \(\kappa(M) \leq 2\sqrt{n}\) for \(M = I + Z^T_{\pm}\) and \(M = I + Z_{\pm}\), and so the multipliers are well-conditioned.

We call the preprocessing \(A \rightarrow (I_n + Z^T_{\pm})^{-1}A\) arithmetic partial pivoting and the two-sided preprocessing \(A \rightarrow (I_n + Z^T_{\pm})^{-1}A(I_n + Z_{\pm})^{-1}\) arithmetic complete pivoting because these two policies emulate partial and complete pivoting, respectively. Namely, we choose a linear combination of row entries or both of row and column entries with coefficients \(\pm\) instead of choosing their absolute maximum in row entries or both of row and column entries, respectively.

7. The inverses of tridiagonal Hermitian or real symmetric matrices \(T\)
are somewhat similar to the inverses of bidiagonal matrices. In particular one can solve both bidiagonal and tridiagonal linear systems of equations in linear arithmetic time \((n - 1)\) and \(9n - 8\), respectively) and in logarithmic parallel time, e.g., by applying the *cyclic reduction* algorithm. By choosing a column-diagonally dominant matrix \(T\) with diagonal filled with 1s and with off-diagonal entries having absolute values at most \(h < 1/2\), we obtain that \(||T||_1 \leq 1 + 2h, \quad ||T^{-1}||_1 \leq 1/(1 - 2h)\) (cf. [GL13, Theorem 4.1.2]), and so \(\kappa_1(T^{-1}) = \frac{||T||_1 ||T^{-1}||_1}{(1+2h)/(1-2h) = 1+4h/(1-2h)}\), which is at most 3 for \(h = 1/4\).

8. A diagonal (or bidiagonal) plus rank-1 matrix or its inverse. Then again such a matrix can be multiplied by a vector by using \(O(n)\) flops, and by choosing a matrix with dominant diagonal, we can bound its condition number as we desire.

We hope that our work will motivate searching for other efficient multipliers and amelioration of the multipliers listed above. The cost of generating random multipliers of the listed classes and their multiplication by the input matrix is significantly smaller than the cost of pivoting, and so we can consider these multipliers *basic building blocks* for multipliers \(F\) and \(H\), which
we can compute as the products and/or sums of small numbers of these blocks. For example, we can choose $H$ being the sum of two blocks of the form $(I + Z_T^T)^{-1}$ or $(I + Z)^{-1}$ plus, possibly, a matrix $cI_n$. Adding the latter term for $c \geq 4n$, say, would ensure that the sum $H$ is diagonally dominant and thus nonsingular and well-conditioned. To increase the power of our preprocessing, we can include the matrices of diagonal scaling and permutation matrices as our basic building blocks. Our tests in Section 4.5 show that such combinations can greatly increase the efficiency of preprocessing.

For a simple example of potential power of such combinations, one can explore variations of PRBT-based multipliers when one allows to use also non-costly permutation multipliers. With this modification, is it possible to stay with one-sided preprocessing and/or decrease the depth $d$ of the recursion without losing the output accuracy?

Another challenge, linked to the dilemma of random versus fixed preprocessing, is in limiting randomization, by using fewer or no random parameters. For example, we can limit randomization of preprocessing $A \rightarrow Z_T^T A$, $A \rightarrow AZ_\pm$, or $A \rightarrow Z_T^T AZ_\pm$ by choosing at random just the signs $\pm$ of the $n - 1$ nonzero subdiagonal entries of the matrix $Z_\pm$, and we can even fix the signs $\pm$ deterministically for all or most of these $n - 1$ entries.

4.4 Randomized circulant preprocessing for symbolic GENP and BGE

Application of GENP in symbolic computations faces no numerical problems and is safe (that is, encounters no divisions by 0) if and only if the input matrix is strongly nonsingular (cf. Theorem 4.2.1). Theorem A.1.1 implies that a Gaussian matrix is strongly nonsingular with probability 1 (over infinite fields) and that a uniform random matrix is strongly nonsingular with a probability close to 1 over finite fields of large cardinality. Therefore, for average input matrix $A$ defined under these probability distributions, GENP and BGE are safe.

Our Theorem 4.4.1 and Corollary 4.4.1 imply that, with Gaussian circulant as well as uniform random circulant preprocessing, GENP and BGE
are likely to be safe universally, that is, for any nonsingular input matrix. We need more than two pages, not counting definitions, in order to prove Theorem 4.4.1, but this enables us to accelerate by a factor of four the preprocessing of [KS91], highly popular among the researchers in symbolic computations, and we also remove one half of random variables involved. Namely, preprocessing of [KS91] requires pre- and post-multiplication of an \( n \times n \) input matrix \( A \) by an upper and a lower triangular Toeplitz matrices, respectively (cf. (??)), at the overall cost dominated by the cost of performing twelve DFT(\( n \)) per row of an input matrix \( A \) (see Remark C.0.1), and in addition one must generate \( 2n - 1 \) random values. We only need to post-multiply a matrix \( A \) by a single circulant matrix, at the cost dominated by the cost of performing three DFT(\( n \)) per row of an input matrix \( A \), and we only generate \( n \) random parameters.

**Theorem 4.4.1.** Suppose \( A = (a_{i,j})_{i,j=1}^{n} \) is a nonsingular matrix, \( T = (t_{i,j+1})_{i,j=1}^{n} \) is a Gaussian \( f \)-circulant matrix, \( B = AT = (b_{i,j})_{i,j=1}^{n} \), \( f \) is a fixed complex number, \( t_1, \ldots, t_n \) are variables, and \( t_k = ft_{n+k} \) for \( k = 0, -1, \ldots, 1 - n \). Let \( B_{l,l} \) denotes the \( l \)-th leading blocks of the matrix \( B \) for \( l = 1, \ldots, n \), and so \( \det(B_{l,l}) \) are polynomial in \( t_1, \ldots, t_n \), for all \( l, l = 1, \ldots, n \). Then neither of these polynomials vanishes identically in \( t_1, \ldots, t_n \).
Proof. Fix a positive integer $l \leq n$. With the convention $\alpha_{k+n} = f\alpha_k$, for $k = 1, \ldots, n$, we can write

$$B_{l,l} = \left( \sum_{k_1=1}^{n} \alpha_{k_1} t_{k_1}, \sum_{k_2=1}^{n} \alpha_{k_2+1} t_{k_2}, \ldots, \sum_{k_l=1}^{n} \alpha_{k_l+l-1} t_{k_l} \right),$$

(4.4.1)

where $\alpha_j$ is the $j$th column of $A_{l,n}$. Let $a_{i,j+n} = f a_{i,j}$, for $k = 1, \ldots, n$, and readily verify that

$$b_{i,j} = \sum_{k=1}^{n} a_{i,j+k-1} t_k,$$

and so $\det(B_l)$ is a homogeneous polynomial in $t_1, \ldots, t_n$.

Now Theorem 4.4.1 is implied by the following lemma.

**Lemma 4.4.1.** If $\det(B_{l,l}) = 0$ identically in all the variables $t_1, \ldots, t_n$, then

$$\det(\alpha_{i_1}, \alpha_{i_2}, \ldots, \alpha_{i_l}) = 0$$

(4.4.2)

for all $l$-tuples of subscripts $(i_1, \ldots, i_l)$ such that $1 \leq i_1 < i_2 < \cdots < i_l \leq n$.

Indeed let $A_{l,n}$ denote the block submatrix made up of the first $l$ rows of $A$. Note that if (4.4.2) holds for all $l$-tuples of the subscripts $(i_1, \ldots, i_l)$ above, then the rows of the block submatrix $A_{l,n}$ are linearly dependent, but they are the rows of the matrix $A$, and their linearly dependence contradicts the assumption that the matrix $A$ is nonsingular.

In the rest of this section we prove Lemma 4.4.1. At first we order the
CHAPTER 4. GAUSSIAN ELIMINATION WITHOUT PIVOTING

$l$-tuples $I = (i_1, \ldots, i_l)$, each made up of $l$ positive integers written in non-decreasing order, and then we apply induction.

We order all $l$-tuples of integers by ordering at first their largest integers, in the case of ties by ordering their second largest integers, and so on.

We can define the classes of these $l$-tuples up to permutation of their integers and congruence modulo $n$, and then represent every class by the $l$-tuple of nondecreasing integers between 1 and $n$. Then our ordering of $l$-tuples of ordered integers takes the following form, $(i_1, \ldots, i_l) < (i'_1, \ldots, i'_l)$ if and only if there exist a subscript $j$ such that $i_j < i'_j$ and $i_k = i'_k$ for $k = j + 1, \ldots, l$.

We begin our proof of Lemma 4.4.1 with the following basic result.

**Lemma 4.4.2.** It holds that

$$\det(B_{l,l}) = \sum_{1 \leq i_1 \leq i_2 \leq \cdots \leq i_l \leq n} a_{\prod_{j=1}^l t_{i_j}} \prod_{j=1}^l t_{i_j}$$

where a tuple $(i_1, \ldots, i_l)$ may contain repeated elements,

$$a_{\prod_{j=1}^l t_{i_j}} = \sum_{(i'_1, \ldots, i'_l)} \det(\alpha_{i'_1}, \alpha_{i'_2+1}, \ldots, \alpha_{i'_l+l-1}), \quad (4.4.3)$$

and $(i'_1, \ldots, i'_l)$ ranges over all permutations of $(i_1, \ldots, i_l)$.

**Proof.** By using (4.4.1) we can expand $\det(B_{l,l})$ as follows,
\[
\text{det}(B_{l,l}) = \text{det}\left( \sum_{k_1=1}^{n} \alpha_{k_1} t_{k_1}, \sum_{k_2=1}^{n} \alpha_{k_2+1} t_{k_2}, \ldots, \sum_{k_l=1}^{n} \alpha_{k_l+l-1} t_{k_l} \right)
\]

\[
= \sum_{i_1=1}^{n} t_{i_1} \text{det}\left( \sum_{k=1}^{n} \alpha_{k+1} t_k, \ldots, \sum_{k_l=1}^{n} \alpha_{k_l+l-1} t_{k_l} \right)
\]

\[
= \sum_{i_1=1}^{n} \sum_{i_2=1}^{n} \sum_{i_l=1}^{n} t_{i_1} t_{i_2} \ldots t_{i_l} \text{det}(\alpha_{i_1}, \alpha_{i_2+1}, \ldots, \alpha_{i_l+l-1}). \tag{4.4.4}
\]

Consequently the coefficient \( a_{\prod_{j=1}^{l} t_{j}} \) of any term \( \prod_{j=1}^{l} t_{j} \) is the sum of all determinants

\[
\text{det}(\alpha_{i_1}, \alpha_{i_2+1}, \ldots, \alpha_{i_l+l-1})
\]

where \((i'_1, \ldots, i'_l)\) ranges over all permutations of \((i_1, \ldots, i_l)\), and we arrive at (4.4.3).

\[
\square
\]

In particular, the coefficient of the term \( t_1^l \) is

\[
a_{t_1^1, t_1^2, \ldots, t_1^l} = \text{det}(\alpha_1, \alpha_2, \ldots, \alpha_l)
\]

This coefficient equals zero because \( B_{l,l} \) is identically zero, by assumption of lemma 4.4.1, and we obtain

\[
\text{det}(\alpha_1, \alpha_2, \ldots, \alpha_l) = 0. \tag{4.4.5}
\]
This is the basis of our inductive proof of Lemma 4.4.1. In order to complete the induction step, it remains to prove the following lemma.

**Lemma 4.4.3.** Let \( J = (i_1, \ldots, i_l) \) be a tuple such that \( 1 \leq i_1 < i_2 < \cdots < i_l \leq n \).

Then \( J \) is a subscript tuple of the coefficient of the term \( \prod_{j=1}^l t_{i_j-j+1} \) in equation (4.4.3).

Moreover, \( J \) is the single largest tuple among all subscript tuples.

**Proof.** Hereafter \( \det(\alpha_{i_1^\prime}, \alpha_{i_2^\prime+1}, \ldots, \alpha_{i_{l-1}^\prime+1}) \) is said to be the determinant associated with the permutation \((i_1^\prime, \ldots, i_l^\prime)\) of \((i_1, \ldots, i_l)\) in (4.4.3). Observe that \( \det(\alpha_{i_1}, \ldots, \alpha_{i_l}) \) is the determinant associated with \( I = (i_1, i_2 - 1, \ldots, i_l - l + 1) \) in the coefficient \( a_{\prod_{j=1}^l t_{i_j-j+1}} \).

Let \( I' \) be a permutation of \( I \). Then \( I' \) can be written as \( I' = (i_{s_1} - s_1 + 1, i_{s_2} - s_2 + 1, \ldots, i_{s_l} - s_l + 1) \), where \((s_1, \ldots, s_l)\) is a permutation of \((1, \ldots, l)\). The determinant associated with \( I' \) has the subscript tuple \( J' = (i_{s_1} - s_1 + 1, i_{s_2} - s_2 + 2, \ldots, i_{s_l} - s_l + l) \). \( j \) satisfies the inequality \( j \leq i_j \leq n - l + j \) because by assumption \( 1 \leq i_1 < i_2 < \cdots < i_l \leq n \), for any \( j = 1, 2, \ldots, l \). Thus, \( i_{s_j} - s_j + j \) satisfies the inequality \( j \leq i_{s_j} - s_j + j \leq n - l + j \leq n \), for any \( s_j \). This fact implies that no subscript of \( I' \) is negative or greater than \( n \).
Let $J'' = \left( s_{r_1} - i_{s_{r_1}} + r_1, s_{r_2} - i_{s_{r_2}} + r_2, \ldots, s_{r_l} - i_{s_{r_l}} + r_l \right)$ be a permutation of $J$ such that its elements are arranged in the nondecreasing order. Now suppose $J'' \geq J$. Then we must have $i_{s_{r_1}} - s_{r_1} + r_1 \geq i_l$. This implies that

$$i_l - i_{s_{r_1}} \leq r_l - s_{r_1}. \quad (4.4.6)$$

Observe that

$$l - s_{r_l} \leq i_l - i_{s_{r_1}} \quad (4.4.7)$$

because $i_1 < i_2 < \cdots < i_l$ by assumption. Combine bounds (4.4.6) and (4.4.7) and obtain that $l - s_{r_1} \leq i_l - i_{s_{r_1}} \leq r_l - s_{r_1}$ and hence $r_l = l$.

Apply this argument recursively for $l - 1, \ldots, 1$ and obtain that $r_j = j$ for any $j = 1, \ldots, l$. Therefore $J = J'$ and $I' = I$. It follows that $J$ is indeed the single largest subscript tuple.

By combining Lemmas 4.4.2 and 4.4.3, we support the induction step of the proof of Lemma 4.4.1, which we summarize as follows:

**Lemma 4.4.4.** Assume the class of $l$-tuples of $l$ positive integers written in the increasing order in each $l$-tuple and write $\det(I) = \det(\alpha_{i_1}, \alpha_{i_2}, \ldots, \alpha_{i_l})$ if $I = (\alpha_{i_1}, \alpha_{i_2}, \ldots, \alpha_{i_l})$.

Then $\det(I) = 0$ provided that $\det(J) = 0$ for all $J < I$. 

Finally we readily deduce Lemma 4.4.2 by combining this result with equation (4.4.5). This completes the proof of Theorem 4.4.1. 

**Corollary 4.4.1.** Assume any nonsingular $n \times n$ matrix $A$ and a finite set $S$ of cardinality $|S|$. Sample the values of the $n$ coordinates $v_1, \ldots, v_n$ of a vector $v$ at random from this set. Fix a complex $f$ and define the matrix $H = Z_f(v)$ of size $n \times n$, with the first column vector $v = (v_i)_{i=1}^n$. Then $\text{GENP}$ and $\text{BGE}$ are safe for the matrix $AH$

(i) with a probability of at least $1 - 0.5(n-1)n/|S|$ if the values of the $n$ coordinates $v_1, \ldots, v_n$ of a vector $v$ have been sampled uniformly at random from a finite set $S$ of cardinality $|S|$ or

(ii) with probability 1 if these coordinates are i.i.d. Gaussian variables.

(iii) The same claims hold for the matrices $FA$ and $F = H^T$.

**Proof.** Theorems 4.2.1, 4.4.1, and A.1.1 together imply parts (i) and (ii) of the corollary. By applying transposition, extend them to part (iii). \qed

**4.5 Numerical Experiments**

Numerical experiments have been designed by the first author and have been performed by Xiaodong Yan for Tables 4.5.1–4.5.4 and 4.6.1–4.6.3 and by the second author for the other tables. The test have been run by using
MATLAB in the Graduate Center of the City University of New York on
a Dell computer with the Intel Core 2 2.50 GHz processor and 4G memory
running Windows 7. Gaussian matrices have been generated by applying
the standard normal distribution function randn of MATLAB. We refer the
reader to [PQZ13], [PQY14], [PQY15], and [PQZa] for other extensive tests
of GENP with randomized preprocessing and of Algorithm 2.3.1.

4.5.1 Tests for GENP

Tables 4.5.1–4.5.4 show the maximum, minimum and average relative resid-
ual norms $||Ay - b||/||b||$ as well as the standard deviation for the solution of
1000 linear system $Ax = b$ with Gaussian vector $b$ and $n \times n$ input matrix $A$
for each $n$, $n = 256, 512, 1024$. The linear systems have been solved by using
GEPP, GENP, or GENP pre-processed with real Gaussian, real Gaussian
circulant, and random circulant multipliers, each followed by a single loop of
iterative refinement.

The tests have been applied to the matrices

$$A = \begin{pmatrix} A_k & B \\ C & D \end{pmatrix},$$

(4.5.1)

with $k \times k$ blocks $A_k, B, C$ and $D$, for $k = n/2$, scaled so that $||B|| \approx ||C|| \approx
||D|| \approx 1$, the $k - 4$ singular values of the matrix $A_k$ were equal 1 and the
other ones were set to 0 (cf. [H02, Section 28.3]), and with Gaussian Toeplitz matrices $B$, $C$, and $D$, that is, with Toeplitz matrices of (??), each defined by the i.i.d. Gaussian entries of its first row and first column. (The norm $\|A^{-1}\|$ ranged from $2.2 \times 10^1$ to $3.8 \times 10^6$ in these tests.) In the tests covered in Table 4.5.4, the matrix $A$ was set to equal $\Omega$, the matrix of DFT$(n)$. For preprocessing, either Gaussian or the unitary Gaussian circulant matrices $C = \Omega^{-1}D(\Omega v)\Omega$ have been used as multipliers, with $v = (v_i)_{i=0}^{n-1}$, $v_i = \exp(2\pi \phi_i \sqrt{-1}/n)$ and $n$ i.i.d. real Gaussian variables $\phi_i$, $i = 0, \ldots, n - 1$ (cf. Theorem C.0.1 and Remark C.0.3).

As should be expected, GEPP has always produced accurate solutions, with average relative residual norms ranging from $10^{-12}$ to $7 \times 10^{-13}$, but GENP with no preprocessing has consistently produced corrupted output with relative residual norms ranging from $10^{-3}$ to $10^2$ for the input matrices $A$ of equation (4.5.1). Even much worse was the output accuracy when GENP with no preprocessing or with Gaussian circulant preprocessing was applied to the matrix $A = \Omega$. In all other cases, however, GENP with random circulant preprocessing and with a single loop of iterative refinement has produced solution with desired accuracy, matching the output accuracy of GEPP. Furthermore GENP has performed similarly when it was applied to a nonsingular and well-conditioned input pre-processed with a Gaussian
multiplier.

We also tested GENP with additive preprocessing applied to the same $n \times n$ test matrices $A$ of (4.5.1), but for $n = 32, 64, 128, 256$. In this case we applied GENP to the matrix $C = A - UV^T$ where $U$ and $V$ were $n \times h$ random Gaussian subcirculant matrices each defined by the $n$ i.i.d. Gaussian entries of its first column and scaled so that $||A|| = 2||UV^T||$. Then we computed the solution $x$ to the linear system $Ax = b$ for a Gaussian vector.

b by substituting the Sherman–Morrison–Woodbury formula (??) into the equation $x = A^{-1}b$.

We present the test results in Table 4.5.5. The results changed little when we scaled the matrices $U$ and $V$ to increase the ratio $||A||/||UV^T||$ to 10 and 100.

Finally we tested GENP with preprocessing by means of some core multipliers of Section 4.3 and some of their numerous possible combinations. We

hope that our study will prompt further research in this direction. The test results are represented in Tables 4.5.6 and 4.5.7.

In this series of our tests we applied GENP to the above matrices of (4.5.1) and six families of benchmark matrices from [BDHT13], pre-processed with multipliers combining the ones of following three basic families.

**Family 1:** Three recursions of the matrices of DFT($n$) with a single random permutation.

**Family 2:** Sparse circulant matrices $C = \Omega^{-1}D(\Omega v)\Omega$, where the vector $v$ has been filled with 0s, except for its ten coordinates filled with ±1. Here and hereafter each sign + or − has been assigned with probability 1/2.

**Family 3:** Sum of two inverse bidiagonal matrices. At first their main
diagonals have been filled with the integer 101, and their first subdiagonals have been filled with ±1. Then each matrix have been multiplied by a diagonal matrix diag(±2^{b_i}), where b_i were random integers uniformly chosen from 0 to 3.

We tested GENP on ten combinations of these three basic families of multipliers, listed below. The size of the linear system was 128. For each combination we have performed 100 tests and have recorded the average relative error \( ||A\mathbf{x} - \mathbf{b}|| / ||\mathbf{b}|| \) with matrices \( A \) from the seven benchmark families and vectors \( \mathbf{b} \) being standard Gaussian vectors. Here are these ten combinations.

1. \( F = I, H \) is a matrix of Family 1.
2. \( F = I, H \) is a matrix of Family 3.
3. \( F = H \) is a matrix of Family 1.
4. \( F = H \) is a matrix of Family 3.
5. \( F \) is a matrix of Family 1, \( H \) is a matrix of Family 3.
6. \( F = I, H \) is the product of two matrices of Family 1.
7. \( F = I, H \) is the product of two matrices of Family 2.
8. \( F = I, H \) is the product of two matrices of Family 3.
9. \( F = I, H \) is the sum of two matrices of Families 1 and 3.
10. \( F = I, H \) is the sum of two matrices of Families 2 and 3.
We tested these multipliers for the same linear systems as in our previous tests in this section and for six classes generated from Matlab, by following their complete description in Matlab and [BDHT13]. Here is the list of these seven test classes.

1. The matrices $A$ of (4.5.1).

2. 'circul': circulant matrices whose first row is a standard Gaussian random vector.

3. 'condex': counter-examples to matrix condition number estimators.

4. 'fiedler': symmetric matrices generated with $(i, j)$ and $(j, i)$ elements equal to $c_i - c_j$ where $c_1, \ldots, c_n$ are i.i.d. standard Gaussian variables.

5. 'orthog': orthogonal matrices with $(i, j)$ elements $\sqrt{\frac{2}{n+1}} \sin \frac{ij\pi}{n+1}$.

6. 'randcorr': random $n \times n$ correlation matrices with random eigenvalues from a uniform distribution. (A correlation matrix is a symmetric positive semidefinite matrix with 1’s on the diagonal.)

7. 'toeppd': $n \times n$ symmetric, positive semi-definite (SPSD) Toeplitz matrices $T$ equal to the sums of $m$ rank-2 SPSD Toeplitz matrices. Specifically,

$$T = w(1) * T(\theta(1)) + \ldots + w(m) * T(\theta(m))$$
where \( \theta(k) \) are i.i.d. Gaussian variables and

\[
 T(\theta(k)) = (\cos(2\pi(i - j)\theta(k)))_{i,j=1}^n
\]

In our tests, for some pairs of inputs and multipliers, GENP has produced no meaningful output. In such cases we filled the respective entries of Tables 4.5.6 and 4.5.7 with \( \infty \).

GENP pre-processed with our multipliers of the 9th combination of three basic families, has produced accurate outputs without iterative refinement for all seven benchmark classes of input matrices. With the other combinations of the three basic families of our multipliers, this was achieved from 4 to 6 (out of 7) benchmark input classes. For comparison, the 2-sided preprocessing with PRBT-based multipliers of [BDHT13] and [BBBDD14] always required iterative refinement.

### 4.5.2 Tests for sampling algorithm with Gaussian and random structured multipliers

Tables 4.6.1–4.6.4 show the results of testing Algorithm 2.3.1 for rank-\( r \) approximation of \( n \times n \) matrices \( M \) for \( n = 256, 512, 1024 \) and \( l = r = 8, 32 \).

The input matrices \( M \), having numerical rank \( r \), have been defined by their SVDs, \( M = S_M \Sigma_M T_M^T \), for \( S_M \) and \( T_M \) generated as \( n \times n \) ran-

Below, generated from Families 1, 2 and 3 of the previous subsection. Namely, we performed Algorithm 2.3.1 for low-rank approximation by using multipliers $B$ obtained as the $n \times r$ western (that is, leftmost) blocks $B$ of the following classes of $n \times n$ matrices.

1. $B$ is a matrix from Family 1.
2. $B$ is a matrix from Family 2.
3. $B$ is a matrix from Family 3.
4. $B$ is the product of two matrices of Family 1.
5. $B$ is the product of two matrices of Family 2.
6. $B$ is the product of two matrices of Family 3.
7. $B$ is the sum of two matrices of Family 1 and 3.
8. $B$ is the sum of two matrices of Family 2 and 3.

The average residual norms are displayed in Table 4.6.4. This shows that the algorithm with our preprocessing has consistently output close approximations to low-rank input matrices. Table 4.6.4 displays the results of the same tests with the multipliers of AH and ASPH transforms of Sections 4.3.6 and ???. We show them separately from the tests of Table 4.6.4 because with these multipliers our preprocessing is performed at particularly low arithmetic cost (see Section ??). Nevertheless the tests produced the results similar to the ones of Table 4.6.4.

Random matrices

A.1 Definitions and expected strong nonsingularity

We use the acronym “i.i.d.” for “independent identically distributed”, keep referring to standard Gaussian random variables just as Gaussian, and call random variables uniform over a fixed finite set if their values are sampled from this set under the uniform probability distribution on it.

Defining a random matrix $H$, we assume that its entries are linear combinations of finitely many i.i.d. random variables, under the Gaussian or uniform probability distribution. The matrix is Gaussian if all its entries are i.i.d. Gaussian variables.

Theorem A.1.1. Assume a nonsingular $n \times n$ matrix $A$ and an $n \times n$ matrix $H$ whose entries are linear combinations of finitely many i.i.d. random
variables.

Let \( \det((AH)_{l,l}) \) vanish identically in them for neither of the integers \( l, l = 1, \ldots, n \).

(i) If the variables are uniform over a set \( S \) of cardinality \( |S| \), then the matrix \((AH)_{l,l}\) is singular with a probability at most \( l/|S| \), for any \( l \), and the matrix \( AH \) is strongly nonsingular with a probability at least \( 1 - 0.5(n-1)n/|S| \).

(ii) If these i.i.d. variables are Gaussian, then the matrix \( AH \) is strongly nonsingular with probability 1.

Proof. Part (i) of the theorem follows from a celebrated lemma of [DL78], also known from [Z79] and [S80]. Derivation is specified, e.g., in [PW08]. Part (ii) follows because the equation \( \det((AH)_{l,l}) \) for any integer \( l \) in the range from 1 to \( n \) defines an algebraic variety of a lower dimension in the linear space of the input variables (cf. [BV88, Proposition 1]).

\[ \square \]

A.2 Rotational invariance and the condition number of a Gaussian matrix

Lemma A.2.1. (Rotational invariance of a Gaussian matrix.) Suppose that \( k, m, \) and \( n \) are three positive integers, \( G \) is an \( m \times n \) Gaussian matrix, and \( S \) and \( T \) are \( k \times m \) and \( n \times k \) orthogonal matrices, respectively. Then \( SG \)
and $G$ and $T$ are Gaussian matrices.

Next we recall some estimates for the norm and the condition number of a Gaussian matrix. For simplicity we assume that we deal with real matrices, but similar estimates in the case of complex matrices can be found in [D88], [E88], [CD05], and [ES05].

Hereafter we write $\nu_{m,n} = ||G||$, $\nu_{m,n}^+ = ||G^+||$, and $\nu_{m,n,F}^+ = ||G^+||_F$, for a Gaussian $m \times n$ matrix $G$, and write $\mathbb{E}(v)$ for the expected value of a random variable $v$.

**Theorem A.2.1.** (Cf. [DS01, Theorem II.7].) Suppose that $m$ and $n$ are positive integers, $h = \max\{m,n\}$, $t \geq 0$, and $z \geq 2\sqrt{h}$. Then

- Probability $\{\nu_{m,n} > z\} \leq \exp(-(z - 2\sqrt{h})^2/2)$ and
- Probability $\{\nu_{m,n} > t + \sqrt{m} + \sqrt{n}\} \leq \exp(-t^2/2)$.

**Theorem A.2.2.** Let $\Gamma(x) = \int_0^\infty \exp(-t)t^{x-1}dt$ denote the Gamma function and let $x > 0$. Then

- (i) Probability $\{\nu_{m,n}^+ \geq m/x^2\} < \frac{x^{m-n+1}}{\Gamma(m-n+2)}$ for $m \geq n \geq 2$,
- (ii) Probability $\{\nu_{n,n}^+ \geq x\} \leq 2.35\sqrt{n}/x$ for $n \geq 2$,
- (iii) $\mathbb{E}(\nu_{F,m,n}^2) = m/|m-n-1|$, provided that $|m-n| > 1$, and
- (iv) $\mathbb{E}(\nu_{m,n}^+) \leq e\sqrt{m}/|m-n|$, provided that $m \neq n$. 

Proof. See [CD05, Proof of Lemma 4.1] for part (i), [SST06, Theorem 3.3] for part (ii), and [HMT11, Proposition 10.2] for parts (iii) and (iv).

Theorem A.2.2 provides probabilistic upper bounds on $\nu^{+}_{m,n}$. They are reasonable already for square matrices, for which $m = n$, but become much stronger as the difference $|m - n|$ grows large.

Theorems A.2.1 and A.2.2 combined imply that an $m \times n$ Gaussian matrix is very well-conditioned if the integer $m - n$ is large or even moderately large, and still can be considered well-conditioned if the integer $|m - n|$ is small or even vanishes (possibly with some grain of salt in the later case). These properties are immediately extended to all submatrices because they are also Gaussian.
Appendix B

Matrices of discrete Fourier transform

**Definition B.0.1.** Write $\omega = \exp\left(\frac{2\pi \sqrt{-1}}{n}\right)$, $\Omega = \Omega_n = (\omega^{ij})_{i,j=0}^{n-1}$, $\Omega^{-1} = \frac{1}{n} \Omega^H$, $\omega$ denotes a primitive $n$-th root of unity, $\Omega$ and $\Omega^{-1}$ denote the matrices of the discrete Fourier transform at $n$ points and its inverse, to which we refer as $DFT(n)$ and $IDFT(n)$, respectively,

$$
\Omega = \Omega_n = \begin{pmatrix}
1 & 1 & 1 & \ldots & 1 \\
1 & \omega & \omega^2 & \ldots & \omega^{n-1} \\
1 & \omega^2 & \omega^4 & \ldots & \omega^{2n-2} \\
\vdots & \vdots & \vdots & \ddots & \vdots \\
\omega^{n-1} & \omega^{2n-2} & \omega^{3n-3} & \ldots & \omega^{(n-1)^2}
\end{pmatrix}.
$$

**Remark B.0.1.** If $n = 2^k$ is a power of 2, we can apply the FFT algorithm and perform $DFT(n)$ and $IDFT(n)$ by using only $1.5n \log_2(n)$ and $1.5n \log_2(n) + n$ arithmetic operations, respectively. For an $n \times n$ input and any $n$, we can perform $DFT(n)$ and $IDFT(n)$ by using $cn \log(n)$ arithmetic operations.
operations, but for a larger constant $c$ (see [P01, Section 2.3]).
Appendix C

$f$-circulant and subcirculant matrices

For a positive integer $n$ and a complex scalar $f$, define the $n \times n$ unit $f$-circulant matrix $Z_f = \begin{pmatrix} 0 & f \\ I_{n-1} & 0 \end{pmatrix}$ and the $n \times n$ general $f$-circulant matrix $Z_f(v) = \sum_{i=0}^{n} v_i Z_f^i$,

$$Z_f = \begin{pmatrix} 0 & \cdots & \cdots & 0 & f \\ 1 & \ddots & 0 & 0 \\ \vdots & \ddots & \ddots & \vdots & \vdots \\ \vdots & \ddots & 0 & 0 \\ 0 & \cdots & \cdots & 1 & 0 \end{pmatrix}$$

and

$$Z_f(v) = \begin{pmatrix} v_0 & f v_{n-1} & \cdots & f v_1 \\ v_1 & v_0 & \ddots & \vdots \\ \vdots & \ddots & \ddots & f v_{n-1} \\ v_{n-1} & \cdots & v_1 & v_0 \end{pmatrix}.$$

$Z_f(v)$ is a lower triangular Toeplitz matrix for $f = 0$, circulant for $f = 1$, and skew-circulant for $f = -1$. $Z^n = fI$ for $I$ denoting the identity matrix,
APPENDIX C. F-CIRCULANT AND SUBCIRCULANT MATRICES

and the matrix $Z_f(v)$ is defined by its first column $v = (v_i)_{i=0}^{n-1}$.

We call an $f$-circulant matrix a Gaussian $f$-circulant (or just Gaussian circulant if $f = 1$) if its first column is filled with independent Gaussian variables. For every fixed $f$, the $f$-circulant matrices form an algebra in the linear space of $n \times n$ Toeplitz matrices $T = (t_{i-j})_{i,j=0}^{n-1}$ (cf. equation (??)).

Hereafter, for a vector $u = (u_i)_{i,j=0}^{n-1}$, write $D(u) = \text{diag}(u_0, \ldots, u_{n-1})$, that is, $D(u)$ is the diagonal matrix with the diagonal entries $u_0, \ldots, u_{n-1}$.

**Theorem C.0.1.** (Cf. [CPW74].) If $f \neq 0$, then $f^n$-circulant matrix $Z_{f^n}(v)$ of size $n \times n$ can be factored as follows, $Z_{f^n}(v) = U_f^{-1}D(U_f v)U_f$ for $U_f = \Omega D(f)$, $f = (f^i)_{i=0}^{n-1}$, and $f \neq 0$. In particular, for circulant matrices, $D(f) = I$, $U_f = \Omega$, and $Z_1(v) = \Omega^{-1}D(\Omega v)\Omega$.

**Corollary C.0.1.** For $f \neq 0$ one can multiply an $n \times n$ $f$-circulant matrix by a vector by applying two DFT($n$), an IDFT($n$), and additionally $n + 2\delta_f n$ multiplications and divisions where $\delta_f = 0$ if $f = 1$ and $\delta_f = 1$ otherwise.

**Remark C.0.1.** We cannot apply this theorem directly to a triangular Toeplitz (0-circulant) matrix, but we can represent such a matrix (as well as any square Toeplitz matrix) as the sum of a circulant matrix and a skew-circulant one and then multiply this sum by a vector at roughly the double computational cost, compared to the case of $f \neq 0$. 
Corollary C.0.2. Let \( D(u) = \text{diag}(u_0, \ldots, u_{n-1}) \) (cf. part (ii) of Definition B.0.1).

(i) If we are given a diagonal matrix \( D(u) \) for \( u = \Omega v \), then we can recover the vector \( v = \frac{1}{n} \Omega^H u \), which defines the entries of the circulant matrix \( Z_1(v) \).

(ii) If the vector \( v \) is Gaussian, then so is also the vector \( u = (u_i)_{i=1}^n = \frac{1}{\sqrt{n}} \Omega v \) (by virtue of Lemma A.2.1) and vice versa. Each of the two vectors defines a Gaussian circulant matrix \( Z_1(v) \).

(iii) By choosing \( u_i = \exp\left(\frac{\phi_i}{\sqrt{2}} \sqrt{-1}\right) \) and real Gaussian variable \( \phi_i \) for all \( i \), we arrive at a random unitary \( n \times n \) circulant matrix \( Z_1(v) \) defined by \( n \) real Gaussian parameters \( \phi_i \), \( i = 0, \ldots, n - 1 \). Alternatively we can set \( \phi_i = \pm 1 \) for all \( i \) and choose the signs \( \pm \) at random, with i.i.d. probability \( 1/2 \) for each sign.

(iv) By adding another Gaussian parameter \( \phi \), we can define a random unitary \( f \)-circulant matrix \( Z_f(v) \) for \( f = \exp\left(\frac{\phi}{2\pi} \sqrt{-1}\right) \).

The following results of [PSZ15] imply that a Gaussian circulant matrix is well-conditioned with a probability close to 1.

Theorem C.0.2. Suppose that \( Z_1(v) = \Omega^H D \Omega \) is a nonsingular circulant \( n \times n \) matrix, and let \( D(g) = \text{diag}(g_i)_{i=1}^n \), for \( g = (g_i)_{i=1}^n \). Then \( \|Z_1(v)\| = \)
APPENDIX C. F-CIRCULANT AND SUBCIRCULANT MATRICES 152

\[ \max_{i=1}^{n} |g_i|, \|Z_1(v)^{-1}\| = \min_{j=1}^{n} |g_j|, \text{ and } \kappa(Z_1(v)) = \max_{i,j=1}^{n} |g_i/g_j|, \text{ for } v = \Omega^{-1}g. \]

**Remark C.0.2.** Suppose that a circulant matrix \( Z_1(v) \) has been defined by its first column vector \( v \) filled with the integers \( \pm 1 \) for a random choice of the i.i.d. signs \( \pm \), each \( + \) and \( - \) chosen with probability \( 1/2 \). Then, clearly, the entries \( g_i \) of the vector \( g = \Omega v = (g_i)_{i=1}^{n} \) satisfy \( |g_i| \leq n \) for all \( i \) an \( n \), and furthermore, with a probability close to 1, \( \max_{i=1}^{n} \log(1/|g_i|) = O(\log(n)) \) as \( n \to \infty \).

**Remark C.0.3.** In the case of a Gaussian circulant matrix \( Z_1(v) \), all the entries \( g_i \) are i.i.d. Gaussian variables, and the condition number \( \kappa(Z_1(v)) = \max_{i,j=1}^{n} |g_i/g_j| \) is not likely to be large. The blocks of the matrix \( Z_1(v) \) are not circulant matrices, and so the latter property is not extended to them, unlike the case of a Gaussian matrix. We can, however, extend the above bound to the condition numbers \( \kappa(B) \) of \( n \times k \) and \( k \times n \) blocks \( B \) of a non-singular \( n \times n \) circulant matrix \( Z_1(v) \), for any positive integer \( k < n \), because \( \kappa(B) \leq \kappa(Z_1(v)) \), for such blocks (cf. [GL13, Corollary 8.6.3]). We call them subcirculant matrices. They are well-conditioned with probability close to 1, and we can even force them to be unitary, while still been defined by by \( n \) i.i.d. Gaussian variables, like the matrices in part (iii) of Corollary C.0.2.
Random subcirculant multipliers have advantage of preserving Toeplitz-like matrix structure (cf. [P01, Chapter 5]) and thus can serve as natural pre-processors for Toeplitz and Toeplitz-like matrices. By using such a multiplier, one can improve a little the recipe in [XXG12, Section 3.2], where a random general rectangular Toeplitz multiplier is applied to a Toeplitz-like input.
